Two broad airway problems can be defined, difficult ventilation and difficult intubation. Difficult mask ventilation was defined by the American Society of Anesthesiologists (ASA)¹ as the inability to maintain the oxygen saturations above 90 percent by face mask inflation with 100 percent inspired oxygen or to reverse signs of inadequate ventilation. Oxygen stores in the body are exhausted within a few minutes and difficult or failed ventilation will rapidly result in morbidity or mortality

from hypoxaemia. Difficult intubation was defined by the ASA as the inability to complete tracheal intubation within three attempts at direct laryngoscopy or within ten minutes. Provided that face mask ventilation is possible, failed tracheal intubation by itself should not result in hypoxaemia unless the failure of airway protection leads to gross airway soiling from gastric contents or blood. Unfortunately, failed tracheal intubation is, in clinical practice, associated with the problems of unrecognized oesophageal intubation, damage to the airway and hypoxaemia.

Difficult intubation may be defined by the number of attempts at direct laryngoscopy or time to achieve intubation, but also by the view of the laryngeal structures seen at direct laryngoscopy. Cormack and Lehane² described the commonly used classification of the best view of laryngeal structures seen at direct laryngoscopy. Grade 1 is visualization of the entire laryngeal aperture, grade II is visualization of the posterior portion of the laryngeal aperture, grade III is visualization of the

epiglottis only and grade IV is no view of any laryngeal structures. Difficult laryngoscopy (and therefore difficult intubation) indicates that it is not possible to see any portion of the vocal cords (grade III/IV) after multiple attempts at conventional direct laryngoscopy.³ A final method of defining difficult intubation is through the need for specialized equipment, often taken as requiring an intubation device other than the standard Macintosh or straight-blade laryngoscope. This has some practical significance because when an anaesthetist fails to intubate by direct laryngoscopy (equipment present in each operating theatre) it is often necessary to use equipment from a difficult intubation trolley located centrally in a theatre complex.

Difficult direct laryngoscopy is only one cause of difficulty with intubation. It may be easy to visualize the larynx but intubation is unsuccessful because the larynx, subglottis or trachea are abnormally narrowed or distorted.

PREVALENCE

Both difficult intubation and difficult ventilation are uncommon. The prevalence of Cormack and Lehane laryngoscopic grade III is 1.5 percent in the general population. Requiring more than three attempts at direct laryngoscopy occurs in approximately 0.4 percent patients and the average anaesthetist will abandon intubation in approximately 1:2500 general surgical patients. In 1200 consecutive ENT and general surgical patients the overall prevalence of difficult intubation (defined as requiring specialist equipment) was 4.2 percent.⁴ The highest prevalence was 12.3 percent in ENT cancer surgery, 3.5 percent in ENT noncancer surgery and 2.0 percent in general surgical patients. This confirms the clinical impression that difficult intubation is more common in patients undergoing head and neck surgery, particularly in those patients following extensive surgery, flap reconstruction and postoperative radiotherapy or with an obstructed airway. [**]

It is difficult to know the precise prevalence of difficult face mask ventilation. Catastrophic failure leading to serious morbidity or mortality is generally quoted as 1:10,000–1:100,00. However, in any large series, a number of problem patients are identified preoperatively and do not receive a general anaesthetic. A North American study involved 18,500 patients of whom 18,200 were intubated under general anaesthesia with 1.8 percent requiring more than two attempts at direct laryngoscopy and no patient being impossible to mask ventilate.⁵ Approximately 300 patients underwent awake intubation and it is this group of patients that is likely to contain those who would have proved difficult to ventilate if anaesthetized. A study of 1502 patients determined a prevalence of difficult mask ventilation of 5 percent but the definition used was that the anaesthetist considered the difficulty was clinically

relevant and could have led to potential problems if mask ventilation had to be maintained for a longer period.⁶

EVALUATION

The aim of airway management is to adequately maintain and protect the airway by use of the face mask, laryngeal mask or tracheal intubation, and preoperative evaluation seeks to initially determine which airway device is required and whether there will be any difficulties in the use or insertion of it. The face mask provides no airway protection and is little used in anaesthesia for head and neck surgery, except for operations such as insertion of grommets. The decision as to whether to use the laryngeal mask or tracheal intubation is taken after considering such factors as the length of surgery, surgical access, requirement for positive pressure ventilation and risk of airway soiling from either blood, pus, cerebrospinal fluid or gastric contents.

The airway may be evaluated according to the scheme outlined in Table 39.1.

History

The anaesthetic or hospital notes may indicate previously encountered difficulty with airway management. The patient may pass on verbal or written information from a previous anaesthetist that they are difficult, or difficulty may be inferred from a history of displaced front teeth, bruised lips, excessive sore throat or an unexpected stay in ITU. Past surgery or radiotherapy, or the current surgical condition, may be relevant if it affects the head, neck or mediastinum. A number of medical conditions, such as rheumatoid arthritis, obstructive sleep apnoea and acromegaly, have some association with difficult airway management. In a prospective study of 128 patients with acromegaly, laryngoscopy was difficult (laryngoscopic view grade III) in 10 percent.⁷ This indicates that the prevalence is six to eight times higher than in normal patients but 90 percent of acromegalics are still easy to intubate. [**] There are a number of congenital

conditions, such as Treacher-Collins and Pierre-Robin, in which airway management, particularly intubation, is often difficult. **Figure 39.1** illustrates a patient with Hunter's syndrome in which abnormal mucopolysaccharide is deposited in the tissues. Characteristically, he was difficult to intubate for a tonsillectomy to alleviate obstructive sleep apnoea and required an emergency tracheostomy in the recovery period. He is pictured in his late teens when his original standard tracheostomy tube had been replaced by one designed to circumvent lower tracheal and carinal deposits. This T-Y silastic stent passes from just below the vocal cords into each main bronchus (an inverted Y shape) with a limb passing out through the tracheostomy (the T component).

Examination

General examination of the patient looks for the features in the following list and the practitioner may be alerted to possible difficulties by various findings:

- trauma, burn, swelling, infection, scarring, haematoma of the mouth, tongue, larynx, trachea or neck;
- large tongue, receding jaw, high-arched palate, prominent upper incisors, short thick neck, large breasts, microstomia, fixed larynx, impalpable

cricothyroid membrane, limited mouth opening, limited head/neck movements;

- voice change, shortness of breath, stridor, inability to lie down.

A number of these factors, such as the appreciation of a short neck or receding jaw (**Figure 39.2**), are subjective. This does not diminish their importance since professional judgements may often be subjective. However, there is a vast literature on prediction of difficult intubation by specific or objective tests. A number have been introduced and the five tests most commonly used are gape, jaw slide, thyromental distance, Mallampati and atlanto-occipital movement.

GAPE

Gape is the measurement of maximal mouth opening and is usually expressed as interincisor distance in finger-breadths or centimetres. Normal values are 3 fb or 5 cm. A mouth opening of 2 fb is limited and 1 fb is severely limited making direct laryngoscopy very difficult. It is difficult to insert a laryngeal mask when the gape is less than 1–1.5 cm (**Figure 39.3**).

JAW SLIDE OR MANDIBULAR PROTRUSION

Functions are graded as follows: class A if the lower jaw can be protruded beyond the top teeth; class B if the lower

Figure 39.1 Mucopolysaccharidosis (Hunter's syndrome).

Figure 39.2 Receding jaw.

© Hodder Arnold / Scott-Brown 7E

Figure 39.3 Limited mouth opening due to dental abscess.

teeth can only reach the top teeth; and class C if the lower teeth will not reach the top teeth. The value of testing this function is that, in intubation by direct laryngoscopy, the lower jaw must slide forward. In some scoring systems, mouth opening and jaw slide are combined, the greatest difficulty indicated by a gape of <3.5 cm and class C jaw slide. Another method of testing mandibular protrusion is the upper lip bite test⁸ in which the patient demonstrates how much of the upper lip may be covered by the lower incisors. Class 1 indicates 'biting' above the vermilion line, class 2 below the vermilion line and class 3 inability to bite the upper lip.

THYROMENTAL DISTANCE

This measurement, described by Patil, is from the mentum to thyroid notch in full neck extension. The normal measurement is 6–7 cm or 3 fb (Figure 39.4). A short distance (2 fb) indicates a 'high' larynx and difficult direct laryngoscopy.

MALLAMPATI

Mallampati's contribution was a test to assess oropharyngeal space. The test asks a seated patient to open their mouth fully and extend the tongue maximally. The practitioner notes which posterior pharyngeal structures are visible. Mallampati described only three grades: class 1 indicates that the posterior pharyngeal wall, fauces and uvula are visible; class 2 indicates that only a part of the fauces, posterior wall and uvula are visible; and class 3 indicates that the tongue meets the palate. Samsoon and

© Hodder Arnold / Scott-Brown 7E

Figure 39.4 A normal thyromental distance.

Young arbitrarily introduced a subdivision of class 3 (tongue against soft palate) and class 4 (tongue meets hard palate).

ATLANTO-OCCIPITAL MOVEMENT

Optimal head and neck positioning for direct laryngoscopy requires cervical spine flexion and almost maximal extension of the head on the spine. A simple clinical test to look at atlanto-occipital movement is for the clinician to ask the patient to flex their neck maximally and then nod; the observer's hand placed posteriorly on the neck makes certain that the nodding motion is at the level of the cranium on the upper cervical vertebrae. Atlanto-occipital extension may be clinically graded as normal or reduced or measured and the normal value is 35° .

Investigations

Plain x-rays may demonstrate abnormalities, such as enlargement of the retropharyngeal space (Figure 39.5), a swollen epiglottis, tracheal deviation or narrowing, a radio-opaque foreign body or obstructive emphysema suggesting a ball-valve obstruction in the relevant bronchus. However, imaging of the whole airway by CT or MR scan is better and will show narrowing or distortion and allow planning of airway instrumentation. Flexible nasendoscopy under topical anaesthesia is extremely useful in delineating supra- or glottic pathology, and a longer flexible fibrescope can inspect the whole respiratory tract although generally this requires sedation.

Another useful test is the flow-volume loop. This expresses flow during expiration and inspiration as a function of lung volume. Airflow is measured during inhalation from residual volume to total lung capacity and exhalation back to residual volume. Extrathoracic obstruction causes limitation of inspiratory flow whilst intrathoracic obstruction causes limitation in expiratory flow. Limitation in expiratory flow is particularly noticeable because the highest flow-rates are usually present in peak expiration.

Figure 39.5 Retropharyngeal abscess.

PREDICTION OF DIFFICULTY

The practitioner forms a professional judgement as to whether airway management plans need to be altered from that carried out normally. It is easy to be definite or accurate in prediction when there are 'barn-door' abnormalities in the past anaesthetic history, past surgical history, examination and current disease process or from imaging. Examples would be a known history of failed intubation, presentation with breathing difficulty or stridor, absent mouth opening or previous head and neck reconstructive surgery. In a study of 181 patients with pharyngolaryngeal disease,⁹ the single most predictive factor of difficult intubation was a tumour in the supraglottic region. In a study of 320 patients with a goitre undergoing thyroid surgery,¹⁰ the presence of tracheal compression, presence of dyspnoea or a cancerous goitre were the three major predictive factors. [**]

However, when there are no abnormalities in the anaesthetic, medical or surgical history, the presenting disease process does not affect the head, neck or mediastinum and the patient does not 'look' difficult, then it is not possible to predict difficulty accurately.

Most attention has been on predicting difficult direct laryngoscopy using various specific or predictive tests

(described above), combination of tests and scoring systems. All are imperfect and the reason is partly the low prevalence of difficult intubation. Test sensitivity indicates the ability of the test to label a difficult patient as difficult, test specificity the ability to label a normal patient as normal and the positive predictive value (PPV) is the proportion of patients found to be difficult out of all patients predicted by that test to be difficult. Table 39.2 shows values of test sensitivity, specificity and PPV for various tests. It can be seen that an individual test, such as Mallampati, has a low PPV indicating that most patients predicted to be difficult will, in fact, be normal. A study comparing the upper lip bite test with the Mallampati in 1425 patients concluded that 'both tests are poor predictors as single screening tests'.¹¹ The more tests that are abnormal increases the likelihood that the patient will be difficult to intubate.

Another approach is to produce a score from consideration of various predictive tests, with appropriate weighting. In Wilson *et al.*'s risk sum,¹² five aspects of examination are used – weight, head and neck movement, jaw movement, receding mandible and buck teeth. Each factor is allocated a score of 0, 1 or 2 depending on severity. Wilson's group suggested that a total score of 2 or more would provide a sensitivity of 75 percent and specificity of 85 percent. These figures may appear to be good but one-quarter of difficult patients will be missed and there will be 1500 false alarms per 10,000 patients. A more recent French study⁴ produced a scoring system involving seven factors – previous difficult intubation, pathologies associated with difficult intubation, clinical symptoms of airway pathology, interincisor gap and mandibular luxation, thyromental distance, maximum range of head and neck movement and Mallampati. The maximum score is 48 and a score of 11 provided the best level of sensitivity and specificity.

The subject of prediction of difficulty is fraught with difficulties arising from studies with small numbers of patients, definitions, curious mathematics and inappropriate conclusions. The topic has been elegantly examined in an editorial which provides a review of the mathematics and an extensive list of references.¹³ A recent meta-analysis of bedside screening tests for predicting difficult intubation in apparently normal patients concludes that they have limited value.¹⁴ [**]

Table 39.2 Test sensitivity, specificity and positive predictive value from the literature and reference 13.¹³

Test	Sensitivity %	Specificity %	PPV %
Thyromental	65–91	81–82	8–15
Mallampati	42–56	81–84	4–21
Wilson risk sum	42–55	86–92	6–9
Mouth opening	26–47	94–95	7–25
Neck movement	10–17	98	8–30

It must be remembered that the objective tests aim only to predict difficult direct laryngoscopy when the tongue has a normal compliance and the respiratory tract is normal. Fixation or restricted movement of the tongue was thought to be the direct cause of failed conventional intubation in a series of five patients¹⁵ and an abnormality, such as a vallecular cyst, may be symptomless and will not be predicted but may cause great problems with airway management.¹⁶ A number of patients who had been found to be unexpectedly difficult to intubate were reviewed and it was discovered that they all had lingual tonsillar hypertrophy.¹⁷

Airway evaluation is an essential part of preoperative assessment. It may be rewarded by the detection of severe or obvious problems that necessitate a change from 'normal' management. When there are no obvious problems, evaluation is imperfect and safe airway management in all circumstances depends on the adoption of an airway strategy that is able to respond to unexpected difficulty with intubation or oxygenation.

STRATEGY

The recommendations of the ASA on management of the airway^{1,3} promoted the five-step linear model of

evaluation of the airway, preparation for difficulty, strategy at intubation, strategy at extubation and follow-up. The ASA difficult airway algorithm presents an overall scheme of planning airway management and a recent version¹⁸ is shown in **Figure 39.6**. The algorithm indicates that airway difficulty may be predicted or unexpected and, in the unexpected limb, attention must first address oxygenation before employing alternative means of intubation. Strategy indicates a combination of plans, also known as plan A/plan B at both initial instrumentation of the airway (induction or intubation) and at the end of surgery (education or extubation). Each plan at the start of anaesthesia addresses ventilation of the patient, the abolition of laryngeal reflexes (if required), the airway device and method of insertion, and the abolition of patient distress. The default strategy when intubation is required is shown in **Table 39.3**. During intubation, there is no ventilation and the patient is oxygenated by intermittent face mask ventilation. Laryngeal reflexes are abolished by muscle relaxation, patient distress is overcome by general anaesthesia and intubation is by optimal direct laryngoscopy. The components of optimal direct laryngoscopy are optimal head and neck position, muscle relaxation, external laryngeal manipulation, laryngoscope blade length/design and use of the gum-elastic bougie. The bougie is the most useful

'low-tech' device (**Figure 39.7**) and it proved successful in 80 percent of the unexpected difficult intubations in one series of 11,257 intubations.¹⁹ Its correct use during attempted direct laryngoscopy is by placement through the glottis, either blindly or by educated guess, confirming placement by feeling the tracheal rings and hold-up at 25 cm when the bougie contacts the carina, followed by railroading the tracheal tube with the laryngoscope still *in situ*.

The components of optimal direct laryngoscopy indicate that a limited number of attempts are possible, perhaps to change the length of blade, use the bougie or apply external laryngeal pressure. However, generally, no more than three attempts should be made and recent evidence in 2833 critically ill patients indicates increased morbidity with more than two attempts.²⁰ The correct decision is to acknowledge 'failed intubation' and abandon plan A. Within default strategy, plan B addresses both failed ventilation and failed intubation by using alternative techniques. In response to the request by the Royal College of Anaesthetists for the display in each hospital of strategies to combat unexpected failed intubation and/or failed ventilation, the Difficult Airway Society (www.das.uk.com) has produced guidelines and flowcharts for the UK.²¹ [*]

ALTERNATIVE TECHNIQUES FOR TRACHEAL INTUBATION

When intubation by direct laryngoscopy fails, a number of alternative techniques should be considered.

Other laryngoscope blade design

The Macintosh curved design is the blade most commonly used by anaesthetists. However, it has a lower success rate than straight blade direct laryngoscopy by the right paraglossal approach. Recently, a British enthusiast, John Henderson, has designed his own straight blade and makes a good case for the reintroduction of the straight blade into mainstream anaesthesia.²² It is a similar technique to that employed by head and neck surgeons, and there seems to be little reason that anaesthetists and surgeons should view the larynx by differing techniques. Another blade, originally invented by McCoy, employs a lever to increase markedly the angulation of the tip (**Figure 39.8**). A number of direct laryngoscopy blades have been introduced over the years incorporating prisms or mirrors to try and provide an indirect view of the larynx but these have not become mainstream devices.

Rigid fibrescopes

Two notable rigid fibrescopes, Upsherscope (**Figure 39.9**) and Bullard, have been introduced. A fibreoptic viewing bundle is incorporated into a rigid curved blade. The tracheal tube is loaded into or onto the device, the blade is introduced into the pharynx and is then positioned under fibreoptic vision. When the tip of the scope has been positioned directly in front of the larynx, the tracheal tube is passed out of its guiding channel or over an introducer into the trachea. The Bullard appears to be the more popular device and has the support of a Canadian consensus group.²³ The device is expensive, training is required and it has not become widely popular in the UK.

Flexible fibrescopes

Tracheal intubation using the flexible fibrescope was first described in 1967 by Peter Murphy,²⁴ an anaesthetic senior registrar working at the National Hospital, Queen Square, London, and flexible intubating fibrescopes have been commercially available for over 20 years. Several textbooks^{25,26} are concerned solely with the technique. A standard adult intubating fibrescope has a length of 60 cm and a nominal external diameter of 4 mm. Its narrow diameter allows it to pass through the nose or mouth, its flexibility allows it to conform to the anatomy of the patient, the working channel can be used to instil local anaesthesia, oxygen or to pass wires in the antero- or

© Hodder Arnold / Scott-Brown 7E

Figure 39.8 McCoy blade with a hinged tip.

retrograde direction to aid intubation, the technique is visual and can be used to confirm correct positioning of the tube in the trachea. It is fairly easy to use anaesthetic breathing system connectors or attachments which allow concurrent ventilation of the patient during intubation, or specially adapted airways to make oral intubation easier. It is not surprising that such an instrument has become the safest and most successful technique of intubation. A Swiss study²⁷ examines the results of 13,248 intubations from one hospital in which the fibrescope is used widely as the primary or back-up intubation technique. The failed intubation rate was 0.045 percent. [**] Ovassapian²⁸ gives figures of 98.4 percent success rate in over 2,000 fibreoptic intubations. The complication rate is extremely low.

Fibre-endoscopic skills appear in the core competencies for trainee anaesthetists and include visual inspection of the respiratory tract for diagnostic purposes and placement of double lumen tracheal tubes. The problems associated with the intubating fibrescope are that some skill is necessary, the device is expensive and repays careful handling, and disinfection requires chemical agents. There has been particular concern over the inability of cold sterilizing agents to destroy prions. The recommendation from the Department of Health is that a

© Hodder Arnold / Scott-Brown 7E

Figure 39.9 Using the Upsperscope.

register should be maintained such that all patients treated with an individual fibrescope can be traced easily.

Intubating laryngeal mask airway

The intubating laryngeal mask was devised by Brain and introduced in 1999. The intubating laryngeal mask airway (ILMA) kit (**Figure 39.10**) differs from the classic laryngeal mask (LM) in several ways. The stem is a rigid highly curved metal tube with a handle, there is an epiglottic elevator bar, a ramp at the junction of the stem and bowl directs the tube appropriately and it is supplied with a special wire-spiral tracheal tube with novel bevel. The described technique of intubation in the anaesthetized, paralyzed patient is for the mask to be placed and the patient ventilated through it. Mask placement appears to be easy provided the mouth opening is more than 2 cm. The tracheal tube is inserted through the stem and advanced slowly without force. As the tip of the tube emerges from the stem, it lifts the epiglottic elevator bar and the route is now clear for the tube to be advanced into the trachea. This blind intubation has a success rate of 95 percent or so if two to three manipulations of mask position and tube advancement are allowed. A fibreoptic modification can be used which allows a visually guided technique and would seem to be preferable. In the largest

Figure 39.10 Components of the intubating laryngeal mask airway.

series of difficult intubations published so far,²⁹ the ILMA was used in 254 patients with a known difficult airway, including 50 patients with airway distortion due to tumour, surgery or radiotherapy. The successful intubation rate was 96.5 percent with a blind technique and 100 percent when used with the fibrescope. [**] Another North American study³⁰ compared intubation by the ILMA in anaesthetized patients with awake fibre-optic intubation in 38 patients with suspected difficult intubation and found them both to be 100 percent successful.

Lighted stylets

The technique of transillumination of the neck to guide oro- or nasotracheal intubation was described first in 1959. A lighted stylet³¹ uses the principle of transillumination and takes advantage of the anterior or superficial location of the trachea. A number of commercially available devices have been produced over the years and the most recent, the Trachlight, appears to be the most successful. The tracheal tube is loaded onto the stylet which has a distal bulb, and the stylet is shaped into a hockey-stick. The lighted stylet is introduced into the oropharynx from the side and brought into the midline. The tip of the lightwand is passed around the tongue and a bright, well-circumscribed circle of light seen externally at the level of the hyoid indicates that the tip lies in the vallecula. The tube is advanced into the trachea without resistance. In one large series of anticipated difficult intubation, successful Trachlight use by the inventor resulted in intubation in 99 percent patients with a mean time of 26 seconds.

ROLE OF THE CLASSIC LM

The classic LM is the most successful of all supraglottic airway devices for maintenance of the airway. In one study of over 11,000 patients, the incidence of failed placement was 1:600 patients. It is, of course, designed for maintenance of the airway in planned, elective surgery. It

	Aintree catheter

has the advantages, when compared with tracheal intubation, of easier placement, no requirement for muscle relaxation and is tolerated *in situ* by the awakening patient. The major disadvantages are that it does not offer the same level of airway protection as a cuffed tracheal tube against gross gastric regurgitation and it does not traverse the larynx, so is no protection against airway occlusion by glottic or infraglottic pathology. It has, however, proved to be a very useful device in difficult airway management and appears in several places in airway algorithms (Table 39.4).

Intubation via the LM

In normal use, the LM should be seated in close proximity to the vocal cords and it is not surprising that it can provide a route for passage of a tracheal tube. There are five methods for this (Table 39.4). A size 6.0 mm will pass through the stem/connector of a size three or four LM and a size 7.0 mm tube will pass through the size five LM. Blind placement, in which the tube is lubricated and advanced blindly, has a success rate of only 50–90 percent and passing a bougie through the LM first has an even lower success rate. Techniques under vision have appreciably higher success rates and flexible fibreoptic techniques are particular useful. The fibrescope may be used to guide placement of a bougie into the trachea with intubation occurring over the bougie.

Fibreoptic-assisted techniques are useful because they are visually guided (Figure 39.11). The core technique is to insert the LM, load a 6.0 mm tube onto the fibrescope, pass the fibrescope into the trachea through the stem of the LM and slide the well-lubricated tube into the trachea. It is also possible to ventilate an anaesthetized patient through the LM whilst intubation is in progress. This introduces the concept of the laryngeal mask as a dedicated airway,³² 'a device used for maintenance of

Figure 39.11 The laryngeal mask is a good conduit for fiberoptic intubation.

Figure 39.12 Aintree catheter – a hollow bougie inserted over a fibroscope.

the airway whilst other airway interventions (e.g. intubation) are in progress'. Development of this concept led to the design of the Aintree catheter,³³ a hollow bougie which may be placed over the fibroscope and inserted through the LM into the trachea (**Figure 39.12**). Effectively, the technique places a hollow bougie under vision into the airway, over which a tracheal tube is railroaded.

FAILED VENTILATION AND EMERGENCY CRICOTHYROTOMY

Failed ventilation refers to the situation where a patient has been anaesthetized and muscle relaxants administered but it is not possible to provide positive pressure ventilation by use of the face mask and oral airway. A prepared sequence of steps should commence to provide rescue oxygenation as quickly as possible. Bag/mask ventilation in which two hands are used to try to maintain airway patency and another hand squeezes the anaesthetic reservoir bag should be followed by insertion of a classic LM. This may prove life-saving and must

always be considered. If oxygenation cannot be achieved by face mask or LM, it may be worthwhile attempting intubation by direct laryngoscopy. This must be a brief attempt only and must not delay oxygenation by the next step. Airway deaths, unfortunately, often involve prolonged fruitless attempts to intubate when oxygenation is the immediate necessity. When the anaesthetized patient cannot be oxygenated by face mask or LM, and tracheal intubation is not possible, emergency oxygenation should be attempted directly into the respiratory tract below the level of the vocal cords. Anaesthetists generally use the cricothyroid membrane (CTM) which has a number of desirable properties:

- superficial;
- easy landmarks to locate;
- present in most patients;
- rarely calcifies;
- relatively avascular;
- wide enough to accept 6.0 mm tube;
- inferior to vocal cords;
- cricoid ring holds airway open;
- posterior lamina protects back wall.

There are three types of cricothyrotomy as detailed in the following sections.³⁴

Needle or small cannula cricothyrotomy

A narrow-calibre rigid needle or flexible cannula is inserted through the CTM in a caudad direction. In adults, an appropriate size is 14 G with an internal diameter of 2 mm (**Figure 39.13**). The resistance to flow through such a calibre is high and this has implications for inspiration and expiration; in inspiration, adequate gas flows cannot be obtained by the pressures generated within a standard anaesthetic breathing system and exhalation of 500 mL takes >30 seconds. Inspiratory gas flows of 500 mL/s require oxygen at a pressure of 2–4 bar supplied by a Sanders injector (**Figure 39.14**). The Sanders injector attaches to the 4 bar (400 kPa, 4 atmospheres) oxygen pipeline and has a hand-operated lever to control gas flow during inspiration. Exhalation occurs through the upper airway and particular attention must be taken to ensure that this happens, otherwise airway pressures rise and pulmonary barotrauma develops. A needle cricothyrotomy is a temporary measure and consideration must be given to creation of a tracheostomy in relevant circumstances. It is possible for ventilation via needle cricothyrotomy to be used in the planned elective or urgent case. **Figure 39.15** shows a patient whose partial denture had fallen into the pharynx in such a position that the larynx was obscured. The cricothyrotomy needle was placed in the awake patient and its correct position in the trachea confirmed by aspiration of free air and attachment of the capnograph to show an appropriate trace. Following intravenous anaesthesia and

© Hodder Arnold / Scott-Brown 7E

Figure 39.13 Ravussin style cricothyrotomy cannula.

© Hodder Arnold / Scott-Brown 7E

Figure 39.14 Sanders injector.

muscle relaxation, the Sanders technique of intermittent application of high pressure oxygen provided adequate oxygenation and ventilation. Exhalation through the upper airway was unobstructed.

Large cannula cricothyrotomy

A purpose-built cannula with an internal diameter of >4 mm allows adequate inspiratory gas flows with the pressures generated by the standard breathing system and exhalation of 500 mL takes approximately 5–6 seconds. This is an advantage because there is no requirement for high pressure oxygen. It is easy to attach the capnograph to the circuit for confirmation of correct positioning within the trachea, and to suction the respiratory tract. Exhalation occurs through the cannula, even in the presence of complete upper airway obstruction. The cannula may be a cannula-over-needle or a Seldinger-type dilatational device. Cannula-over-needle devices place an uncuffed tube whereas the Melker Seldinger device allows positioning of a 6.0 mm cuffed tube. There are advantages in placing a cuffed tube in allowing controlled positive pressure ventilation and protecting the airway.

© Hodder Arnold / Scott-Brown 7E

Figure 39.15 Planned use of transtracheal jet ventilation.

Surgical cricothyrotomy

The technique is to make a 3 cm midline incision in the skin followed by a horizontal stab incision in the inferior part of the cricothyroid membrane. The incision is spread horizontally and vertically and a 6 mm tube is inserted. The complication rate was 40 percent in one series of 38 emergency surgical cricothyrotomies. Misplacement and bleeding requiring ligation of vessels were the most common problem. A more rapid four-step technique has been described³⁵ in which a single horizontal incision is made through the skin and cricothyroid membrane together. In a cadaver study, emergency physicians compared the standard and rapid technique. The rapid technique was faster than the standard 43 versus 134 seconds, but the complication rate was higher. The horizontal incision through the skin may cause more haemorrhage. A cricothyrotomy tube should not be left in place for more than a few days and conversion to tracheostomy prevents the complications of dysphonia and subglottic stenosis.

OBSTRUCTED AIRWAY

The obstructed airway³⁶ is one in which the primary symptoms or signs are due to narrowing or distortion of the airway. There are two broad clinical presentations. In acute obstruction (**Figure 39.16**), a previously normal person develops problems over a matter of minutes or hours. The aetiology is usually one of inhaled foreign body or abnormal fluid accumulation, such as blood, pus or oedema. Typical clinical scenarios are infections in the head and neck, postoperative haematoma, and airway swelling secondary to anaphylaxis or angiotensin-converting enzyme inhibitors. The rapidity of onset produces prominent signs of difficulty with breathing and the patients may present in extremis. Imaging of the airway by x-ray, CT or MR scan is often inappropriate because

© Hodder Arnold / Scott-Brown 7E

Figure 39.16 Patient with Ludwig's angina.

the patient may be unable to adopt the necessary position to complete the procedure and the radiology suite is not an appropriate location for a patient with a deteriorating airway. The management of acute obstruction includes 100 percent oxygen by face mask, trial of administration of heliox, nebulized adrenaline (epinephrine) if oedema is prominent, drainage of pus, tracheal intubation or emergency cricothyrotomy or tracheostomy. Heliox is a combination of oxygen 21 percent and helium 79 percent and is three times less dense than air because of the low atomic weight of helium (4) compared with nitrogen (14). In airway obstruction, turbulent gas flow is inversely proportional to the square root of density and the use of heliox improves gas flow in turbulent conditions and also promotes laminar flow. It is suggested also that carbon dioxide molecules diffuse four to five times faster through heliox than an equivalent oxygen–nitrogen mixture and this may enhance carbon dioxide excretion in the airway.

In chronic obstruction, the airway pathology has developed over a period of weeks or months and is usually due to growth of tissue or to scarring. The slow onset allows development of enlarged intercostal muscle mass and patients can tolerate a very significantly narrowed airway without symptoms. Generally, a patient will not be dyspnoeic at rest until the airway is narrowed

to <5 mm diameter, although they are likely to be short of breath on exercise. The slower time course of obstruction allows complete imaging of the airway and controlled intervention. Appropriate imaging in the stable, chronic condition is through flexible nasendoscopy and CT or MR imaging of the entire airway. Flow-volume loops may be helpful in detecting that a patient's problem is large airway narrowing and not truly pulmonary, or assessing the degree of tracheal narrowing before planning surgery.

Evaluation of the obstructed airway seeks to define the degree of obstruction, likely site, rapidity of onset and likely time course of deterioration by history, examination and special investigations. The history from the relative or patient usually indicates whether this is acute, chronic or acute-on-chronic. Specific symptoms/signs in airway obstruction are degree of difficulty with breathing, stridor (noisy breathing) and phase of respiration of any stridor. Stridor indicates that the airway is narrowed to <50 percent normal diameter, but this degree of airway narrowing is not always accompanied by stridor. Expiratory stridor indicates an infraglottic problem and inspiratory stridor a supra or glottic aetiology. There may be a positional aspect to the difficulty with breathing and patients may be more comfortable in the sitting or lateral position. Voice change and difficulty with swallowing may indicate the site or extent of disease, and pyrexia or sepsis indicates an infective component. Unilateral reduction in breath sounds in the chest indicate specific bronchial obstruction. With progressive obstruction, signs of ineffective ventilation and poor gas exchange are present. These include agitation, anxiety, confusion, restlessness and depressed level of consciousness. Increased work of breathing is indicated by a high respiratory rate, use of accessory muscles of respiration, flaring nostrils, sweating and tachycardia. Oximetry is not a good monitor of work of breathing and normal oxygen saturation does not indicate that all is well. In severe acute obstruction with untrained respiratory muscles, exhaustion occurs relatively quickly with a resulting decrease in effective minute ventilation, hypoxaemia, bradycardia and death.

Management strategy in the obstructed airway

The Confidential Enquiry into Perioperative Deaths (CEPOD) report³⁷ 1996/97 examined 30 patients who had died within 30 days of surgery for management of lesions in the upper airway or who presented with stridor. In most cases death was due to the underlying disease process but in some cases difficulties with maintenance of the airway led to death in the operating theatre or recovery unit. Brief case scenarios are given in the report and one describes a 76 year-old patient with fixed cervical spine flexion (due to rheumatoid arthritis) and a retrosternal goitre. After induction of anaesthesia with thiopentone and muscle relaxation with suxamethonium,

the patient proved impossible to intubate and mask ventilate adequately. An emergency tracheostomy proved difficult and cardiac arrest occurred in theatre.

The surgical and anaesthetic assessors made several good recommendations. The patients should be seen by the consultant surgeon and anaesthetist who consider carefully the plan for securing the airway. Imaging of the airway should be obtained, if possible, to allow delineation of whether the airway is narrowed at supraglottic, glottic or infraglottic level. Airway strategy should include a primary and back-up plan with coherence between the individual plans. If a long-acting muscle relaxant is used in plan A, plan B cannot rely on a patient 'waking-up'. If a surgical tracheostomy is the back-up plan, anaesthesia should start in the operating theatre with the equipment, surgeon and theatre team immediately ready – it is foolish to start anaesthesia in the anaesthetic room and scramble into theatre when plan A fails. [*]

There has been much discussion in the anaesthetic literature about provision of anaesthesia in the presence of the abnormal airway but general agreement that classification according to the site of obstruction is helpful. Currently, the terms used by anaesthetists are not as precise as the ones used by surgeons to localize tumours.

'SUPRAGLOTTIC' OBSTRUCTION

In 'supraglottic' obstruction the obstruction is above or superior to the glottis and the glottic aperture is of normal dimensions. An example would be a base of tongue tumour (**Figure 39.17**), although clearly this is not truly a supraglottic structure in disease terminology. Direct laryngoscopy is likely to prove difficult and may cause bleeding if the blade contacts the tumour. It may also prove difficult to ventilate by face mask following induction of general anaesthesia. In this circumstance it is helpful to retain spontaneous respiration and to use an alternative means of intubation. Awake fiberoptic intubation (**Figure 39.18**) by the nasal or oral route has much

to recommend it³⁸ and was used successfully in a series of 26 adult patients with deep neck infections including classical Ludwig's angina.³⁹ [**]

Awake intubation is a misnomer because it is very difficult to intubate a truly awake patient. The more correct term is tracheal intubation under topical anaesthesia with conscious sedation. It has a very good record of safety in airway management because the patient maintains their own airway and continues with spontaneous respiration until the airway is secure. It is possible for the patient to adopt a change in position, such as sitting up, and to aid intubation by protruding their tongue, vocalizing or taking deep breaths. There are a number of intubation techniques in an awake patient, such as oral direct laryngoscopy, blind intubation through the nose, through the classic or intubating laryngeal masks or a retrograde wire technique. Awake fiberoptic intubation appears to be the best technique, combining awake intubation with a visually guided method of both inspecting and intubating the airway, applying local anaesthesia to the airway and confirming correct positioning of the tube within the trachea. Fiberoptic intubation is generally easier in the awake rather than anaesthetized, paralysed patient because airway patency is maintained, the airway opens and closes with respiration and the flow of gas indicates the route to the larynx.

There are a number of specific practical steps and attention to detail is required. Premedication may be employed if there is no airway embarrassment, but should be avoided if there are symptoms or signs of airway obstruction. An antisialogogue is important and absence of secretions allows earlier and more profound topical anaesthesia, and easier fibre-endoscopy. Preoperative

Figure 39.17 Magnetic resonance image of tongue base tumour.

Figure 39.18 Awake fiberoptic intubation.

intramuscular atropine 0.6 mg, hyoscine 0.4 mg or glycopyrrolate 0.4 mg are suitable but it is common to administer glycopyrrolate 0.2–0.4 mg intravenously as soon as the patient arrives in the operating room.

Sedation aims to provide a comfortable patient who maintains spontaneous respiration, airway patency and verbal contact. Small incremental doses of a benzodiazepine and opioid are administered, taking care not to produce oversedation. Typical total doses are midazolam 1–5 mg and fentanyl 25–100 µg. Both drugs have a peak onset of five minutes and a specific antagonist (flumazenil and naloxone, respectively). Benzodiazepines cause relaxation of genioglossus and destabilization of the airway and opioids are associated with central respiratory depression so neither drug is benign. However, appropriate doses produce a compliant patient who is not unduly upset by airway topicalization or instrumentation, and is usually amnesic. Propofol, an anaesthetic agent, provides sedation at subhypnotic concentrations and is particularly useful when given by target-controlled infusion. Target controlled infusion (TCI) devices are sophisticated syringe pumps which incorporate a pharmacokinetic model of the relevant drug. The operator enters the age and weight of the patient and the desired blood level. The TCI pump calculates and delivers the appropriate bolus dose to reach the required blood level and the subsequent infusion required to maintain it. Appropriate starting blood levels for propofol are 0.5–1.0 µg/mL. Remifentanyl, an ultrashort-acting opioid, may also be used by TCI and is gaining a reputation as a useful opioid for awake intubation. If the nasal route is chosen for intubation, a topical vasoconstrictor should be applied. This may be xylometazoline or ephedrine 0.5 percent drops or cocaine (3 mL 5 percent), which produces both vasoconstriction and topical anaesthesia.

Topical anaesthesia may be provided by:

- nebulization;
- translaryngeal administration;
- specific nerve blocks;
- transendoscopic administration.

Nebulization sounds attractive but use of the technology which provides particles for alveolar deposition of drug (e.g. salbutamol nebulizer), may lead to disappointing results partly because the particles are too small but also because a large amount of the drug escapes to the atmosphere. High-drug concentrations may be effective and nebulized lignocaine 10 percent in a dose of 6 mg/kg has been described as effective. A useful variant is the production of a larger droplet size produced during inspiration. This manual spray-and-inhale technique employs a 22 g Venflon attached to a constant oxygen flowrate of 1–2 L/min. Small increments of lignocaine 4 percent are injected through the port of the cannula and coordinated with inspiration. One spray-and-inhale regime is to use 3 mL lignocaine 4 percent with ephedrine 15 mg to the nose, wait three minutes and apply the

second 3 mL lignocaine 4 percent, asking the patient to inspire deeply and slowly through the nose. The droplets are inhaled and deposited onto the larynx and trachea. After a three minute wait, a further 3 mL lignocaine 4 percent is nebulized during slow forced inspiration. Maximum lignocaine dosage should be 9 mg/kg.

Translaryngeal administration has a long history of safe use. A study reviewing 17,500 administrations reported only six noteworthy complications.⁴⁰ A 22 G cannula or needle is passed through the cricothyroid membrane or trachea and 3–4 mL lignocaine 4 percent is injected preferably at end-expiration. The injection provokes a short period of intense coughing which distributes the drug to the glottis and above. The experimental addition of methylene blue to the local anaesthetic shows staining of the superior aspect of the vocal cords in 95 percent of patients.

Appropriate specific nerve blocks are of the superior laryngeal and glossopharyngeal nerves. The internal branch of the superior laryngeal nerve supplies sensation to the under surface of the epiglottis and the superior surface of the vocal cords. It may be blocked on each side as it traverses the thyrohyoid membrane. Extension of the head and neck aids identification of the hyoid and thyroid cartilages. A 22 G needle is placed inferiorly to the greater horn of the hyoid, passed into the membrane and 2 mL lignocaine 2 percent is injected. The glossopharyngeal nerve supplies sensation to the posterior third of the tongue, superior part of the epiglottis, lateral pharyngeal wall and inferior surface of the soft palate. The nerve may be blocked behind the anterior pillar of the tonsillar fossa. With full mouth opening the tongue is grasped and pulled to the contralateral side. A 20 G spinal needle is inserted to a depth of 5 mm into the base of the anterior tonsillar pillar at the level of the reflection onto the tongue, and 2 mL lignocaine 2 percent injected. Bilateral glossopharyngeal nerve blocks will abolish the gag reflex and allow greater manipulation in the oropharynx or direct laryngoscopy, perhaps when placing a large double lumen tube. These specific nerve blocks are not performed routinely.

Transendoscopic administration of lignocaine 4 percent through the working channel of the intubating fibrescope is an extremely effective means of applying local anaesthetic to the airway under vision. This spray-as-you-go technique is highly favoured and noninvasive. The intubating fibrescopes have connectors for injection but an easier alternative is to place an epidural catheter, cut to produce one terminal hole, substantially into the working channel (**Figure 39.19**). Aliquots of lignocaine 4 percent to a maximum dose of 9 mg/kg are administered.

It is helpful for the fibrescope to be attached to a CCTV system, particularly for training. An appropriate size tracheal tube is loaded onto the fibrescope and the scope is introduced under vision into the mouth or more patent nostril. The fibrescope is advanced without

© Hodder Arnold / Scott-Brown 7E

Figure 39.19 Injection of lignocaine through an epidural catheter inserted into working channel of fibroscope.

touching the mucosa until the vocal cords are seen. Additional local anaesthetic may be applied before the fibroscope is advanced to the carina. The tube is advanced or railroaded over the fibroscope. This may be difficult because the bevel impinges on the larynx. Use of a small diameter tube and rotation of the tube minimize this problem.

Awake fibreoptic intubation may be difficult when the airway anatomy is abnormal and when there is blood or secretions in the airway. An illustrative case scenario indicates some of the pitfalls in management. An adult patient underwent removal of a fishbone impacted in the lower pharynx/upper oesophagus. Three days later the patient was pyrexial, with a sore throat, unable to swallow and with limited mouth opening. A lateral x-ray of the neck showed a retropharyngeal abscess. The patient was seen by two anaesthetic trainees who did not inform the consultant on call. They decided on an awake fibreoptic intubation but administered too much sedation. In a deteriorating situation with a semirousable patient they attempted nasal fibreoptic orotracheal intubation (FOI) with the patient supine. They were unsuccessful and were moved aside by the consultant surgeon who managed to intubate the patient fibreoptically with the patient sitting, leaning forward on the edge of the operating table. Mistakes made here include failure to appreciate the seriousness of the condition and to inform a consultant, failure to realize that awake nasal FOI in the supine position would be difficult in the presence of retropharyngeal swelling and failure to realize that airway patency would be compromised by any sedation.

PERIGLOTTIC/GLOTTIC OBSTRUCTION

In these situations it may be difficult to visualize the vocal cords by direct laryngoscopy and the glottic aperture may be significantly narrowed or distorted. Much lively discussion is evident over the correct anaesthetic technique. When awake fibreoptic intubation is used, it allows visualization of the airway but becomes less useful

in the patient with stridor due to glottic narrowing. The fibroscope has little rigidity to 'push' through a narrow hole and attempts to do this may precipitate bleeding and oedema. If the scope is passed through a small hole, the airway is completely obstructed for a short time and patients feel uncomfortable at this stage. There have been a few reports^{41,42} of destabilization of the airway by applanasthetic agent to the airway and this is a reminder of the need to work at all times in the correct environment for immediate activation of the preformulated back-up plan. Awake fibreoptic intubation is, therefore, a technique which should always be considered but may not be suitable. It is not appropriate when adequate operator skill is not present, in children and uncooperative adults and in the opinion of some anaesthetists when stridor is present.

Mason and Fielder⁴³ argue that the correct anaesthetic technique in the presence of stridor due to periglottic/glottic pathology is inhalational induction of general anaesthesia. [*] This permits a gradual onset of anaesthesia and maintains spontaneous respiration, even at a depth of anaesthesia appropriate for direct laryngoscopy and intubation. The maintenance of spontaneous respiration is viewed as highly desirable with supraglottic airway obstruction. A typical case scenario would be a child with epiglottitis and, in a survey of college tutors in the UK, 98 percent of anaesthetists would choose this form of anaesthesia. The face mask is applied to the patient who is in the most comfortable position (sitting if necessary) and 100 percent oxygen administered for a few minutes. The volatile agent is administered in increasing concentrations until a surgical level of anaesthesia is obtained. The agent commonly used initially is either halothane or sevoflurane and both drugs are nonirritant so do not provoke coughing. The speed of onset of anaesthesia is inversely proportional to the blood-gas solubility and is therefore faster with sevoflurane (0.6) than halothane (2.4). However, it is more difficult to establish sufficient depth of anaesthesia to instrument the airway with sevoflurane and it has a more rapid offset than halothane. Halothane may be associated with increased cardiac rhythm irritability and is now difficult to obtain in the UK. It is usual, therefore, to start with sevoflurane but change over to isoflurane which does permit adequate levels of anaesthesia.

It is not an easy anaesthetic to administer in the presence of stridor and requires a sanguine anaesthetist. There may be periods of increasing obstruction due to glottic irritability or change in position. Generally, there should be no change in the position of the anaesthetist's hands or the face mask and no attempt in light planes of anaesthesia to provide positive pressure ventilation. Insertion of an oral airway is risky but there may be benefit in a nasopharyngeal airway, although it is perhaps useful to have applied a vasoconstrictor to the nasal mucosa first. Glottic irritability is confined to light planes of anaesthesia and should resolve, although induction

may take much longer than normal because of the reduced alveolar ventilation. When an adequate depth of anaesthesia is reached, which may take 20 minutes, direct laryngoscopy is undertaken. The view may be quite abnormal and it may be necessary to press on the chest and observe the egress of bubbles to detect the glottis. A small tube will be needed and the use of a bougie should be considered. If intubation is not possible, the face mask is reapplied and a tracheostomy undertaken. Plan B must be formulated and ready so that anaesthesia is induced in the operating theatre with the surgeon scrubbed and ready to undertake tracheostomy.

It is apparent that the safety of any approach is the combination of plans and the close cooperative working of the surgeon, anaesthetist and theatre team. In the common scenario of a known obstructing glottic tumour which requires initial histology and debulking, it is possible to construct a primary plan of (in the operating theatre) preoxygenation, followed by intravenous induction and rapid muscle relaxation. Direct laryngoscopy using a bougie and size 5.0 mm microlaryngeal tube is attempted. If it is unsuccessful, the surgeon is in the best situation to undertake tracheostomy – the patient is as well oxygenated as possible, unconscious and remains still. This technique is logical and popular but appears ‘heretical’ since it abolishes spontaneous respiration. However, it illustrates that safety lies in the combination of plans rather than any particular plan A, that the site of obstruction requires plans which are specific for that level of obstruction and the safety which arises from the close working of experienced surgeon and anaesthetist.

There is an increasing evidence-base to the practice of planned prior placement of a transtracheal ventilation catheter under local anaesthesia and using this as a route for oxygenation and ventilation during intubation attempts under general anaesthesia. The technique was used in 11 patients over 22 months in one institution with great success.⁴⁴ [**]

TRACHEOSTOMY UNDER LOCAL ANAESTHESIA

This should be considered in any patient with an obstructed airway. It is particularly appropriate as the primary plan when the disease process is a large friable mass or abscess in the supraglottis or glottis and intubation attempts may destabilize or compromise the airway. There are differences between countries and between surgeon–anaesthetist pairs as to when the patient undergoes traditional intubation in the awake or anaesthetized state or awake tracheostomy. Elements within the decision making are the availability of a skilled fibre-endoscopist, the ability of the patient to cooperate with the procedure and adopt a suitable position, the pretracheal anatomy and the likely time for resolution of the disease process. It may be a very difficult procedure in

patients with short stocky necks, a previous tracheostomy or post-radiotherapy with respiratory distress.

Tracheostomy under local anaesthesia is undertaken in the operating theatre with the patient breathing oxygen or heliox, monitored by noninvasive blood pressure, ECG and pulse oximetry with intravenous access. A semisitting position with a roll under the shoulders and neck extension is ideal. Generally, reassurance is given to the patient but intravenous sedation is not required and should be used cautiously. Restlessness during the procedure may be due to hypoxia, hypercarbia or an inability to breathe in that position. Sedation may destabilize the airway leading to sudden hypoxia and loss of consciousness. The anaesthetist must be prepared for the back-up plan if the patient deteriorates. Placement of a cricothyrotomy needle at the outset may be useful when it is known that the pathology is supraglottic. The cricothyrotomy needle does not interfere with a surgical tracheostomy and can be used to provide oxygenation. If the patient becomes so restless that the surgeon is unable to operate, consideration should be given to providing general anaesthesia and oxygenation through the needle.

Another option in the distressed patient is to provide sedation/anaesthesia by addition of a volatile anaesthetic agent, such as sevoflurane, to the breathing system with 100 percent oxygen. At best, the airway proves to be adequate enough to allow a surgical plane of anaesthesia to be reached and the tracheostomy is undertaken in a relatively unhurried fashion on 100 percent oxygen/sevoflurane by face mask. At worst, the airway deteriorates with the onset of sedation/anaesthesia but the patient stops moving and a rapid emergency tracheostomy can be undertaken. In a rapid tracheostomy, the surgeon enters the airway with one or two incisions and a small cuffed microlaryngeal or armoured tube size 5.0–6.0 mm is inserted. Once the patient has been stabilized, a more measured exploration of the neck and fashioning of a formal tracheostomy may be undertaken.

It is important to verify that the tube is within the trachea before ventilation starts otherwise gas may be forced into the mediastinal tissues. Signs of correct placement when undertaking a tracheostomy under local anaesthesia (with the patient breathing spontaneously) are firstly regular respiratory movement of the reservoir bag of the anaesthetic breathing system connected to the tracheostomy tube, and the presence of six successive breath-related carbon dioxide traces on the capnograph. If no carbon dioxide is detected in the breathing system, inflation of the cuff of the tracheal tube or tracheostomy and connection of the capnograph to the breathing system should be checked first. If both are correct, failure to detect carbon dioxide indicates that the tube is not in the airway. When an emergency tracheostomy is undertaken in an apnoeic patient, the confirmatory signs of anaesthetic bag movement and capnography can be obtained only by applying a number of positive pressure breaths. If the tube is not within the trachea, these

positive pressure breaths into the mediastinum may prove deleterious. An alternative confirmatory device in these circumstances, although not widely used, is the oesophageal detector device. The principle is simple and takes advantage of the structural differences between the oesophagus and trachea. In the original version described by Wee in 1988, an empty 60 mL syringe is attached to the 15 mm connector of the inserted tracheal tube and aspiration attempted. Aspiration of air is not possible if the tube is in the oesophagus because the mucosa is 'sucked' over the end of the tube, whereas the more rigid cartilaginous structure of the trachea allows free aspiration of air. The syringe can be replaced by a self-inflating bulb with a volume of approximately 75 mL and in this version the bulb is squeezed flat before being attached to the inserted tube. If the bulb reinflates immediately, the tube is in the trachea and if the bulb does not reinflate the tube is in a false passage or the oesophagus.

SUBGLOTTIC AND MIDTRACHEAL OBSTRUCTION

Imaging is particularly useful in delineating the length of narrowing, the diameter of the airway at its narrowest and that sufficient distance is present inferiorly to the obstruction to permit the cuff of a tracheal tube to be positioned above the carina. The obstruction may arise from external pressure, such as a retrosternal goitre or other mediastinal mass, from a mass arising from the trachea, from an inflammatory condition such as Wegener's granulomatosis, from previous surgery or from damage due to prolonged intubation. The type of narrowing may range from a short subglottic stenosis due to previous prolonged intubation to a narrowing of several centimetres in the midtrachea due to tumour. In the presence of stridor, the principles of management vary according to whether it can be bypassed by tracheostomy. This will be true for subglottic disease but the CEPD assessors noted that in two patients it had been difficult to bypass a mid/low

tracheal lesion with a standard length tracheostomy tube. Awake fibreoptic intubation has a role in management of trachea narrowing, allowing inspection of the airway and confirmation that the tip of the tracheal tube has passed beyond the obstruction. Rigid bronchoscopy is an extremely effective means of managing these patients.

LOW TRACHEAL OBSTRUCTION

Narrowing of the lower trachea or carina presents great difficulty. The anaesthetic literature contains case reports of failed airway maintenance leading to death.⁴⁵ This characteristically occurs after induction of general anaesthesia or muscle relaxation when, presumably due to loss of muscle tone, airway patency is lost. Tracheal intubation may not provide an adequate airway because the obstruction is beyond the tip of the tube. Occasionally, the presence of carinal obstruction is not known and anaesthetic induction, intubation or indeed extubation may result in unexpected disaster. When imaging has provided good preoperative localization of obstruction, a number of options may be used. Rigid bronchoscopy is invaluable and will often provide a route for ventilation (**Figure 39.20**). The rigid bronchoscope may also act as a guide to therapy, such as lasering of a tumour or introduction of a tracheobronchial stent. Surgical resection of carinal lesions requires specialist anaesthetic techniques including jet ventilation and undertaking surgery during cardiopulmonary bypass.

EXTUBATION AND RECOVERY

At the end of surgery a decision is made as to where and when the airway device should be removed. There is little problem with removal of a laryngeal mask. This is usually tolerated well by a patient until they are awake. Tracheal intubation is common in head and neck surgery due to

Figure 39.20 Rigid bronchoscopy used for ventilation and conduit for tracheal stent.

the constraints of providing clear operative fields for the surgeon and maintaining a secure airway to the distal trachea. Extubation requires as much thought, and gives rise to as much difficulty, as intubation. Transient difficulties with oxygen saturations are common due to coughing, breath-holding and laryngospasm, particularly in children. Extubation problems may arise in those patients who were difficult to intubate and those who were not difficult to intubate but in whom surgery has affected the airway.

Default strategy at extubation when no difficulty is expected is for the anaesthetist to remove any pharyngeal packs, suction the pharynx under direct vision, administer 100 percent oxygen, antagonize residual neuromuscular blockade and consider whether to remove the tube in the anaesthetized or awake state. After extubation, 100 percent oxygen is administered by face mask and the patient observed by the anaesthetist until it is clear that the patient is safe to go to the post-anaesthetic care unit (Recovery).

In the patient with a normal airway who was difficult to intubate, it is prudent to make certain that oxygen stores are maximal and to extubate in the awake state. Lung oxygen stores can be considered maximal when the end-tidal (i.e. alveolar) oxygen is 91 percent. This may take at least five minutes of breathing 100 percent oxygen or longer if nitrous oxide has been used. Awake extubation refers to removal of the tracheal tube when the person has opened their eyes and is able to obey commands. An additional option is to assess the leak around the tube before removal. This may be carried out by applying positive pressure to the tube, deflating the cuff and listening for egress of gas around the tube, or alternatively occluding the tube in spontaneous respiration and making certain that inspiration can occur around the tube. Failure of a leak test indicates that the tube is a very tight fit within the airway and an inadequate air passage may be left after extubation.

In the patient with an abnormal airway, either present preoperatively or due to surgery, consideration should be given to keeping the tracheal tube *in situ* for 24–48 hours until any airway oedema subsides. The patient should be nursed in a high-dependency unit with an appropriate level of sedation to avoid inadvertent removal of the tube. In some circumstances it is appropriate to perform a tracheostomy to provide a secure airway in the first few postoperative days.

Extubation of the high-risk airway requires a strategy. Awake extubation after maximal oxygenation in the presence of an anaesthetist in a well-equipped environment may be a good plan A, but what happens if it fails? The situation rapidly becomes critical with a struggling, hypoxic patient possibly with blood in the oropharynx. One possibility is to extubate over a thin bougie and to leave the bougie in the airway for a period until it is certain that the patient is coping satisfactorily. The bougie acts as a guide if reintubation is required and, if it is hollow, may be used for emergency oxygenation.

Problems may arise in the Recovery unit or post-operatively on the ward. Of most concern is postoperative bleeding following carotid endarterectomy or removal of a parapharyngeal mass. The physical presence of a mass of blood may compress the airway itself but also induces mucosal oedema, perhaps by impairment of lymphatic drainage. The deterioration of the airway may be very dramatic and necessitate emergency cricothyrotomy or tracheostomy as part of resuscitation. In a dire situation it is always worth fitting an LM. It is helpful to open the wound and evacuate the blood clot and this may provide temporary improvement. The patient is returned to theatre for surgical exploration. Intubation should take place with the patient breathing spontaneously, if possible. This may be by awake intubation or with inhalational anaesthesia. Blood in the pharynx may impair the view and the first response is to try suctioning. An LM may cover the larynx and provide some respite before being used as a conduit for intubation. Emergency tracheostomy may be required (**Figure 39.21**). In this patient, drainage of a peritonsillar abscess had been undertaken with intubation by awake fiberoptic intubation. The patient had been extubated and returned to Recovery. Approximately 45 minutes later, the patient developed severe breathing difficulties and was returned immediately to the operating theatre. Awake intubation was not possible due to soiling of the airway, the patient was too restless to adopt a position suitable for formal tracheostomy and, in a deteriorating situation, the surgeon managed to carry out a rapid emergency tracheostomy.

FOLLOW-UP

Following difficulties with airway management, a certain scheme should be followed. An account of the problem and management should be written in the anaesthetic record and in the hospital notes. The patient needs to be reviewed clinically to detect and treat any morbidity, an explanation is required for the patient with details of the problem encountered and management, and a written

Figure 39.21 Post-extubation emergency tracheostomy.

account should be sent to the patient with a copy to their general practitioner.⁴⁶ If the problem with airway management is likely to be recurrent with subsequent anaesthetics, consideration should be given to the patient registering with Medic Alert and wearing a bracelet or to registering the patient with the difficult airway database supported by the Difficult Airway Society. [*]

Immediate morbidity or mortality from difficult airway management arise from the effects of severe hypoxia, hypercarbia or cardiovascular responses, from failure to adequately protect the airway leading to aspiration and from physical trauma to the airway during attempts at intubation or resuscitation. Airway damage may occur even when airway management has not been notably difficult. Valuable information can be obtained from detailed analysis of the medical information contained in insurance reports, once claims for negligence have been settled or closed. In an analysis of such closed claims in North America,⁴⁷ 6 percent of 4460 claims were for airway injury. The most frequent sites of injury were the larynx (33 percent), pharynx (19 percent) and oesophagus (18 percent). Approximately 20 percent of laryngeal injuries were associated with difficult intubation and included granuloma formation, arytenoid dislocation and hoarseness. Injuries to the pharynx and oesophagus had a much stronger association with difficult airway management. Half of all pharyngeal injuries and 68 percent of pharyngeal perforations were associated with difficult intubation.

There were five deaths in the pharyngeal injury claims and all involved perforation and the development of mediastinitis. The oesophageal injuries involved a significantly greater proportion of females and patients older than 60 years than the other sites and oesophageal perforation involved difficult intubation in 67 percent of claims. Oesophageal injuries were the most severe and were associated with a poor outcome with 19 percent mortality. Pharyngo-oesophageal perforation is a serious condition (overall mortality 25 percent) and risk factors include difficult intubation, emergency intubation and intubation by inexperienced personnel. Perforation may also be caused by passage of a nasogastric tube. The triad of surgical emphysema, chest pain and pyrexia should be sought and treatment with antibiotics, limitation of oral intake and surgical review initiated as soon as possible. In the closed claims study, surgical emphysema was only evident in 56 percent of patients and the diagnosis was sometimes delayed. It is suggested that treatment within 24 hours improves outcome. [*]

KEY POINTS

- The difficult airway is an important feature in head and neck surgery.
- Difficult intubation and difficult mask ventilation are different entities.

- Evaluation of the airway is imperfect and may fail to predict difficulty.
- Airway obstruction may be acute or chronic.
- Imaging of the airway is essential, when possible, to delineate the level of obstruction.
- Airway strategy means a primary plan A and back-up plan B.
- The anaesthetic room is an inappropriate location for plan A if plan B is a surgical tracheostomy.
- Pharyngo-oesophageal perforation due to intubation attempts has a high mortality and needs early detection and treatment.

Best clinical practice

- ✓ All patients should undergo airway evaluation as part of preoperative assessment.
- ✓ Strategy must cover unexpected failed intubation and failed ventilation.
- ✓ The LM is a versatile airway device and should always be available.
- ✓ Decisions about management of the obstructed airway are made by senior anaesthetists and surgeons.
- ✓ Awake fibreoptic intubation and tracheostomy under local anaesthesia should be considered in the obstructed airway.
- ✓ Maintenance of spontaneous respiration is recommended when general anaesthesia is employed in the presence of upper airway obstruction.
- ✓ Consider placement of a transtracheal ventilation catheter prior to inducing general anaesthesia in the difficult upper airway.
- ✓ Always confirm correct placement of the tube in the trachea.
- ✓ A strategy is required for extubation.
- ✓ Follow-up is important to detect and treat morbidity caused by airway management.

Deficiencies in current knowledge and areas for future research

- Unified surgical and anaesthetic terms describing the location of disease pathology in the airway.
- Randomized comparative studies of anaesthetic techniques in management of the obstructed airway.
- National collection of serious adverse incidents resulting from airway management in head and neck disease.

- National audit of attempts at emergency cricothyrotomy.
- Annual publication of circumstances of death within 28 days of surgery for the obstructed airway.

SEARCH STRATEGY AND EVIDENCE-BASE

The search strategy for the evidence in the chapter was by Medline search of the key words anaesthesia, ear, nose, throat and maxillofacial, and combinations of the words. Reference lists of retrieved papers were searched manually as were reference lists of standard text (listed in the reference list at the end of the chapter).

As is the case with anaesthesia in general the evidence levels are largely from observational, nonexperimental, noncontrolled studies or expert opinion (i.e. levels 3 and 4), or in the case of clinical evidence from low-quality case-controlled/cohort studies or clinical series and expert opinion (i.e. grades C and D). This arises purely due to the paucity of randomized controlled trials or metaanalyses of the common questions covered in this chapter.

PRINCIPLES OF GENERAL ANAESTHESIA

Anaesthesia is a relatively modern specialty. Before the mid-nineteenth century, the scope of operative surgery was small. The advent of anaesthesia, however, facilitated a revolution in surgical practice. Although anaesthetic techniques have changed considerably since this time, the basic principles that underpin the practice have changed little. Modern anaesthetic practice encompasses many things, including perioperative system support, monitoring, postoperative intensive care and pain relief. However, the roots of anaesthetic practice lie in the simple

requirement to **facilitate successful surgery**. The main aims to this end are summarized in the triad of surgical anaesthesia below:

1. to abolish consciousness, implicit and explicit memory (= hypnosis);
2. to prevent movement (= akinesia);
3. to obtund the subconscious response to pain, stress and trauma (= analgesia).

These are both functional and humanitarian aims. The principal benefit to the pioneering surgeon was the abolition of movement in their patients, so now for

the first time, subtle and delicate procedures could successfully be undertaken. The abolition of consciousness and recall is a clear humanitarian benefit to the patient, and the obtunding of the response to pain produces better operating conditions as well as having other advantages.

Early anaesthesia, to some extent, achieved all three of these aims with a single agent, namely ether. Given in sufficient dosage, ether could produce surgical anaesthesia achieving hypnosis, akinesia and, to some extent, analgesia. The drawback with this kind of 'single-agent anaesthesia' was that the doses of ether required to achieve all these was often perilously high.

In contrast, modern anaesthesia tackles the triad of anaesthesia using a combination of drugs or agents to satisfy each of the aims separately. This has become known as 'balanced anaesthesia' and is depicted in Figure 40.1.

In balanced anaesthesia, the 'anaesthetic vapour' (such as halothane or isoflurane) is used merely to depress cognitive function and provide the element of 'hypnosis'. This is achieved at relatively low concentrations; far below those required to achieve akinesia and analgesia and far below concentrations associated with respiratory depression and cardiovascular collapse.

The element of analgesia is provided by specific drugs (such as the opioid fentanyl or the opiate morphine), or by supplemental use of regional or local anaesthetic blocks.

This combination of hypnotic and analgesic drugs may be sufficient also to provide akinesia, i.e. to abolish movement in response to stimulus, and yet the patient may still breathe spontaneously. However, there are occasions when it is desirable to abolish all movement and to relax the tone in all skeletal muscle, for example to facilitate endotracheal intubation and permit mechanical

ventilation. This can be achieved by specific drugs which block the neuromuscular junction and paralyse skeletal muscle such as atracurium or vecuronium. When the element of akinesia is provided in this way, it is possible to reduce the doses of hypnotic and analgesic drugs yet further. So by judicious use of hypnotics, analgesics and muscle relaxation, a state of balanced anaesthesia can be achieved in which the dose of anaesthetic agent is a fraction of that which would be required if it were used as a sole agent.

PREMEDICATION

Until relatively recently, premedicant drugs were used religiously and routinely as an accompaniment to general anaesthesia. This habit probably stemmed from the necessity of using such drugs when ether inhalation was standard practice.

The need for anxiolysis

Induction of anaesthesia by inhalation of ether and chloroform was a lengthy process, and many patients still have unpleasant memories of it. As these experiences entered the folklore, patients often became more anxious about their impending anaesthetic than their surgery.

The need for an antisialogogue

In addition, inhalation of the early anaesthetic agents produced copious secretions which was not only undesirable to the ENT surgeon, but also made spontaneous respiration via a face mask a challenge for the anaesthetist.

The need for an antiemetic

Ether is a particularly potent emetic. Even modern volatile agents can contribute to postoperative nausea and vomiting.

The need for an opiate

In modern anaesthesia, rapidly acting, lipid soluble synthetic opioids can be used to produce desired levels of analgesia with precision. By contrast, the traditional opiates (morphine, omnopon, etc.) used in early anaesthesia have a slow onset of action and so were best given an hour or so before the onset of surgery to ensure adequate analgesia. Such opiates were not usually given intraoperatively in any significant dose because, since most patients breathed spontaneously via face masks, any depression of respiration was considered undesirable.

Figure 40.1 Balanced anaesthesia.

Table 40.1 Modern premedicant drugs.

Analgesics		Gastric alkalinizers	Prokinetics/antiemetics	Anxiolytics
NSAIDs	Paracetamol			
NSAIDs are widely used in the perioperative period. They are remarkably effective and relatively safe when used in healthy patients for a short duration. Although many preparations can be given rectally, they are well absorbed from the stomach and best, and most economically, given orally if possible	This is a safe and effective analgesic which can be given orally with an NSAID one hour preoperatively	Aspiration of even small volumes of acid gastric fluid can produce severe respiratory complications. All patients with a history of gastro-oesophageal reflux should receive prophylactic treatment to reduce gastric acidity. Many anaesthetists would routinely do this for all patients H ₂ blockers, e.g. ranitidine Proton pump inhibitors, e.g. omeprazole Sodium citrate. This is a 'buffer' which mops up acid and is given, if indicated, immediately pre-induction.	Metoclopramide is a dopamine antagonist, which increases gastric motility and emptying and has antiemetic properties. The evidence is not clear whether the benefits of such drugs justify their prophylactic use	The best anxiolysis is provided by good communication between doctor and patient. Well-informed and reassured patients will seldom require pharmacological anxiolysis. Where indicated, it is usually provided by oral drugs, e.g. benzodiazepines such as temazepam

The combination of intramuscular omnopon and scopolamine ('om and scop') was for many years the 'pre-med' of choice for adult anaesthesia, since it combined analgesia, anxiolysis, antiemesis and the drying of secretions.

Modern anaesthetic drugs and techniques are now so finely honed that the traditional 'pre-med' is rarely required and is seldom used. However, in some cases premedication with other drugs is indicated (see Table 40.1).¹

- Antiemetic and antacid prophylaxis can usefully be given preoperatively to high-risk patients.

KEY POINTS

- Sedative premedication is seldom used in modern anaesthetic practice, especially as day-case surgery is increasing.
- Pre-emptive analgesia (from simple agents such as nonsteroidal antiinflammatory drugs (NSAIDs) and paracetamol) are usefully given preoperatively to provide early postoperative pain relief.

ANAESTHETIC AGENTS

Intravenous agents

Intravenous (i.v.) anaesthetic agents can be used to induce and/or to maintain anaesthesia, although they are more commonly used for induction alone. For many years, the barbiturate thiopentone dominated this class of drugs. However, by far the most commonly used i.v. induction agent in the western world is propofol, which is a derivative of phenol. Most induction agents are extremely lipid soluble, and this accounts for their rapid onset of action, since they are delivered to the brain with a high blood flow and diffuse into it (the brain being principally lipid) with ease. Plasma levels then fall rapidly. This is not due to rapid metabolism, but rather because the drug

redistributes (via the large cerebral blood flow) to other lipid-rich tissues with lower blood flows. Metabolic clearance accounts for a much slower 'background' elimination of drug and reduction in the brain-drug levels.

Propofol is so lipid soluble that it cannot easily be dissolved in aqueous media. For this reason it is prepared as a lipid emulsion and this accounts for its milky appearance.

As well as being used for induction, propofol can be infused intravenously to maintain anaesthesia. This is an increasingly popular technique and can be associated with more rapid clear-headed recovery and a reduction in postoperative nausea. Like most anaesthetic agents, thiopentone and propofol are associated with a fall in blood pressure mediated by a number of mechanisms, including reduction in central sympathetic vasomotor tone and reduction in cardiac contractility. These features are particularly marked in the elderly and patients who are hypovolaemic and dehydrated.

KEY POINTS

- Intravenous induction agents owe their rapid onset and offset of action to rapid diffusion across the blood–brain barrier due to their high lipid solubility.
- Hepatic clearance is moderately slow, and does not play a significant part in the return of consciousness after a bolus dose of intravenous agent.

INHALATIONAL AGENTS

Inhalational or 'volatile' agents may be used for induction and/or maintenance of anaesthesia, although they are more commonly used for maintenance alone. The historical archetype is 'ether' (actually diethyl ether) but the more commonly used modern agents such as isoflurane and sevoflurane are also ethers (halogenated methyl-ethyl ethers). Like the intravenous agents, the volatile agents are lipid soluble: the higher the lipid solubility, the higher the potency. Modern agents are extremely lipid soluble and so their potency is sufficiently high to require only 1 or 2 percent concentration in the inspired gas to induce anaesthesia. The depth of anaesthesia is determined by the partial pressure (i.e. the effective concentration) of the volatile agent in the brain. Since the brain is in equilibrium with the arterial blood, and the latter is in equilibrium with the alveolar gas, then the depth of anaesthesia should be determined by the partial pressure (or concentration) of volatile agent in the alveoli. Given that we can easily measure the

concentration of anaesthetic vapours in the alveoli (i.e. in the expired breath), we can therefore reliably determine and estimate the anaesthetic depth with precision and confidence. In contrast, we have no means of doing this for i.v. agents.

Volatile agents can also be used to induce anaesthesia, and some do so more quickly than others. We have already stated that the depth of anaesthesia is determined by the partial pressure of the agent in the alveoli/blood/brain. In the blood, only molecules that are not in solution contribute to the partial pressure. As soon as a molecule of gas or vapour enters solution in the blood, it is effectively 'hidden' and no longer contributes to the partial pressure. This is analogous to the absorbency of a sponge. When water is absorbed into the sponge it no longer contributes to its external 'wetness'. A large volume of water will need to be added to a highly absorbent sponge before it contributes to its external wetness, whereas only a small volume needs to be added to a poorly absorbent sponge before it appears wet.

So, for agents which are highly soluble in blood (such as traditional ether or halothane), the partial pressure in the blood will be slow to rise because almost as fast as the molecules of gas diffuse across the lung into the blood, they enter solution and are effectively hidden, thus failing to contribute to the partial pressure. Conversely, modern agents, such as sevoflurane, have a low blood solubility. As these molecules enter the bloodstream, only a few enter solution, the remainder do not, and therefore contribute to the partial pressure in the blood. Consequently, the arterial partial pressure rises and equilibrates rapidly with the alveolar gas. In turn, the high partial pressure in the arterial blood equilibrates with the brain and induction occurs rapidly. In summary, modern agents have a high lipid solubility (and hence high potency) and low blood solubility (and hence allow rapid induction).²

The sections above outline the drugs that can be used to induce and maintain anaesthesia. The following section outlines how anaesthetic technique is planned for some common or important ENT operations, with a particular emphasis on management of the patient's airway. One of the hallmarks of anaesthesia for ENT surgery is the concept of the 'shared airway': the surgeon operates in the same anatomical region as the anaesthesia airway devices are situated. Therefore, the detailed properties of the airway device selected and precise conduct of anaesthesia are particularly important to ENT surgery as compared with many other types of surgery.

KEY POINTS

- Older agents (ether, halothane) have high solubility in blood and therefore a slow onset and offset of action.

- Modern agents (sevoflurane, desflurane) have low solubility in blood and therefore rapid onset and offset of action.
- Because of our ability to measure vapour concentrations in the expired breath, adequate depth of anaesthesia can be determined with confidence.

Figure 40.2 Laryngeal mask airway.

DEVICES USED IN AIRWAY MANAGEMENT

The simple face mask

Induction of anaesthesia invariably results in a degree of collapse of the upper airway resulting in airway obstruction. This is largely due to the reduction in tone of the pharyngeal dilator muscles and genioglossus. These muscles are innervated by the efferent outflow of the 'respiratory centre', and tone varies cyclically in much the same way as does the diaphragm under the command of the phrenic nerve. Drugs that depress the respiratory centre and have a tendency to produce a 'central' apnoea, also by this mechanism, have a tendency to produce an 'obstructive' apnoea. Central and obstructive apnoeas are therefore inextricably linked, and cannot adequately be categorized as separate entities.³

If neuromuscular blocking drugs are also used, then spontaneous ventilation is abolished completely. All these factors require the use of devices that give both anatomical support to the upper airway and also facilitate ventilation. Perhaps the simplest means of achieving these aims is a face mask which, when connected to a suitable supply of oxygen and/or anaesthetic gas, may be used to support the airway manually or (if spontaneous ventilation is absent) allow hand-ventilation of the patient's lungs. Problems with the face mask technique are that it does not allow good surgical access to the face, head or airway; it requires that one or both of the anaesthetist's hands are occupied in airway maintenance and active ventilation of the patient's lungs can be often inefficient (i.e. not all the tidal volume administered to the patient enters the lungs, and some is lost as a 'leak').

Supraglottic airway devices

A range of supraglottic airway devices (SADs) have been developed which reduce some of these problems. In general, these are tubes (often with inflatable distal components to 'hold' the airway in place) that lie in the oropharynx, above the level of the glottis. The device most commonly used is the laryngeal mask airway and others include the cuffed oropharyngeal airway and the Pro-sealTM laryngeal mask (Figure 40.2). SADs allow

spontaneous breathing and, similar to the face mask technique, facilitate active ventilation by hand. However, since SADs lie above the glottic opening and do not seal it, there is a risk that prolonged positive pressure ventilation of the lungs (for example, if the SAD is connected to a mechanical ventilator) may cause air to enter the oesophagus and stomach. If gastric fluid should then regurgitate, SADs will not completely protect the airway from lung soiling. There is currently a debate concerning the role of some SAD devices in positive pressure ventilation, and some authorities argue that their use during positive pressure ventilation is, in fact, justified.⁴

Tracheal tubes

There is a range of tracheal tubes available (Figure 40.3). These tubes lie in the trachea and (usually) have a small cuff at the distal end, whose purpose it is to protect the airway from soiling (for example by blood or regurgitant gastric contents) and to improve the efficiency of ventilation by minimizing leaks. Tracheal tubes vary in shape, size and the material from which they are made, and these factors are important in relation to their specific use.

CUFFED VERSUS UNCUFFED TUBES

Generally speaking, cuffed tubes are used in adult anaesthesia, and 'plain' or uncuffed tubes are used in prepubertal children for the following reason. In adults, the narrowest part of the larynx is at the level of the vocal cords, and so if a tube can be passed between the cords, one can be confident that at any point distal to the vocal cords, the tube will be sitting loosely and will not be wedged-in, causing epithelial damage. The high-volume, low-pressure cuff can be inflated to provide a loose seal at this level. In children however, the narrowest part of the larynx is at the level of the cricoid cartilage and not at the vocal cords. It is, therefore, quite possible to pass a tracheal tube which is small enough to pass through the cords with ease, but which may be wedged-in at the level of the cricoid, and this may cause epithelial oedema or necrosis at this level. This is particularly problematic in small airways because any further reduction in calibre in an already small airway produces a disproportionately

© Hodder Arnold / Scott-Brown 7E

Figure 40.3 Tracheal tubes. (a) A cuffed RAE tube. The tube is preformed in a 'south-facing' curve so that the anaesthetic breathing system passes out of the way of the surgical field; (b) a 'north-facing' RAE tracheal tube; useful if the anaesthetist and the breathing system are 'north' of the patient's head and the surgeon is working from the 'south'; (c) a microlaryngeal tube. This has an internal diameter of 5 mm and is sufficiently narrow to allow the vocal cords to be inspected during panendoscopies; (d) a reinforced tracheal tube. Note the metallic spiral in the wall of the tube that allows it to be bent in any direction without kinking the lumen.

greater increase in airflow resistance, since this is inversely related to the fourth power of the airway radius.

In order to confirm that the tracheal tube is sitting loosely at all points in the larynx, plain tubes are used and one deliberately seeks to allow a small leak. This should be audible on inflation of the chest under positive pressure and excludes the possibility that the tube is exerting any circumferential pressure on the laryngeal epithelium at its narrowest point. The disadvantages of having this small leak is that ventilation may not be as efficient and the lower airway is not definitively secured and protected from soiling from above. For this reason, if the type of surgery permits, the laryngeal inlet can be packed with damp ribbon gauze.

Since tracheal tubes form a sealed conduit into the trachea, they are primarily used when the patient is paralysed and requires positive pressure ventilation (there is no risk of blowing air into the stomach). It is indeed possible to allow the patient to breathe spontaneously through a tracheal tube, but since the glottis and trachea are richly innervated, deep anaesthesia is required to prevent the patient from reflex coughing. The doses required to achieve this may lead to dose-related side effects (as described above). Whereas most SAD devices can be used effectively after relatively short periods of training, the techniques used by the anaesthetist to insert a tracheal tube are more specialized and are described in more detail in Chapter 39, Recognition and management of the difficult airway. Tracheal tubes may be passed either orally or nasally, and these routes are important and can depend upon the type of surgery performed (for example, a nasotracheal tube facilitates better surgical access for dental surgery, but is clearly a hindrance during operations on the nose).

Regardless of which airway device is selected, it is vital that there is constant communication between surgeon

and anaesthetist regarding the other's needs during surgery (and also at the stage of planning an operation). The airway device must not hinder the surgical process because of its size or shape; it must be properly secured in place to prevent dislodgement during head movement by the surgeon; and the direction of the airway device shaft must be appropriate to the operation. Use of surgical gags and props may compress the airway device, so the anaesthetist must be vigilant about the patency of the airway. Airway obstruction may occur not only during induction of anaesthesia, but also after extubation of the trachea or recovery and it is often especially important that the surgeon is present in the operating room at extubation.

Factors influencing choice of device in airway management

In general terms, patient factors and surgical factors dictate the choice of which of the above devices is used in anaesthetic airway management.

PATIENT FACTORS INFLUENCING CHOICE OF AIRWAY DEVICE

There are a number of factors or signs in the patient which would suggest to most anaesthetists that a tracheal tube (with the patient consequently artificially ventilated), rather than a SAD device (with the patient breathing spontaneously), should best be used.

Gastro-oesophageal reflux

Hiatus hernia, peptic ulcer disease, symptomatic reflux, pregnancy, recent ingestion of solids or particulate liquids,

abdominal sepsis or injury all predispose to regurgitation of gastric contents during induction of anaesthesia. Tracheal intubation (as part of a 'rapid sequence' induction of anaesthesia) would minimize the risk of lung soiling.

Obesity

Obese patients do not always find it easy to breathe when lying supine, even when awake. This difficulty is exacerbated when anaesthetized, and artificial positive pressure ventilation (necessitating tracheal intubation) is therefore often necessary.

Patients with known or anticipated difficult airway

In any patient whose trachea is known or anticipated to be difficult to intubate, it is reasonable to formulate a plan to intubate the trachea during induction of anaesthesia and so achieve a definitive, 'secured airway' in the patient before surgery begins. While it is also acceptable (and sometimes necessary should tracheal intubation fail) to use a SAD device, the problem is that should tracheal intubation subsequently be necessary urgently during the course of surgery, this might be difficult or impossible to achieve in a short space of time.

SURGICAL FACTORS INFLUENCING CHOICE OF AIRWAY DEVICE

A number of surgical requirements reasonably influence the choice of airway device.

Factors related to the 'shared airway'

For certain operations, it is necessary for the surgeon to have an unobstructed view of the relevant anatomy. Most SAD devices (as a result of the large distal cuff) do not permit a good view of structures distal to the oropharynx. Thus, for almost all periglottic, laryngeal and subglottic operations, a tracheal tube is more suitable or necessary. SAD devices may, however, be used for operations related to the tonsils, anterior tongue, nose, teeth and ears without obstructing the surgical field.

Laser surgery

Standard (polyvinyl chloride) tracheal tubes are not laser-resistant and may ignite if struck by the laser beam. A number of specialized tracheal tubes have been developed which are more laser-resistant. The materials used include various metals, Teflon and ceramics. Some recent work suggests that the flexible laryngeal mask airway is also suitably laser-resistant and, if used in the presence of laser, its distal cuff should be filled with saline (or methylene blue dye so that rupture can be easily detected). Anaesthesia for laser surgery is further discussed below under Laser surgery.

Requirement for neuromuscular blockade

For certain operations (for example abdominal surgery) it is necessary that the patient's muscles are fully flaccid to facilitate surgery. This is best achieved by use of

neuromuscular blocking drugs. Since these also paralyse spontaneous ventilation, artificial mechanical ventilation is required; an endotracheal tube is most commonly used to facilitate this. While strict muscle relaxation of the degree needed in abdominal surgery is rarely required in ENT surgery, there are some operations in which it is desirable to minimize risk of the patient moving, coughing or swallowing (for example skull base surgery, any ENT operation in combination with neurosurgery or pharyngeal surgery). This is most reliably achieved by using neuromuscular blocking drugs.

Neuromuscular blockade and facial nerve monitoring

For certain ENT operations, such as vestibular schwannoma resection, middle ear, mastoid and parotid surgery, it is necessary that the surgeon is able to monitor the integrity of the facial nerve and minimize the risk of damaging it during surgery. For this purpose, needle electrodes are placed in the orbicularis oculi and oris muscles that detect EMG potentials generated in these muscles as a result of surgical or electrical stimulation of the facial nerve. The electrical activity evoked in these muscles is amplified and converted into an audible signal by the monitor. By this means, the surgeon is warned of the impending proximity of the nerve should he be unaware of its precise position, and can use the sound signal to moderate his handling of the nerve in those situations where this is necessary. At the completion of surgery the electrical integrity of the nerve can be assessed by proximal stimulation. In addition, it is possible to identify the site of a neuropraxia and, by varying the intensity of the stimulating current, assess its severity. A block that can be overcome by increasing the stimulation current is probably not as bad as one that cannot. Obviously, it is impossible to monitor facial nerve activity in the presence of complete neuromuscular blockade. Partial blockade can be overcome by decreasing the stimulation frequency from 30 to 3 Hz, but information derived in this state may be unreliable.

From the anaesthetic standpoint, if direct nerve monitoring is necessary, it is advisable to avoid long-acting neuromuscular blocking drugs altogether during surgery. If tracheal intubation is required, it is possible to use a short-acting muscle relaxant to facilitate intubation on the premise that the effect will have worn off by the time monitoring is required by the surgeon. Offset of muscle relaxation should be confirmed by using a peripheral nerve stimulator to stimulate the ulnar nerve (Figure 40.4) and feeling forceful contraction of adductor pollicis. Alternatively, intubation may be accomplished without muscle relaxants by administration of high doses of opioids or volatile anaesthetic agents. An infusion of remifentanyl, a very potent and ultra-short acting opioid, often produces good conditions for intubation and allows stable levels of anaesthesia during surgery. In some cases it will be possible to avoid intubation by the use of a supraglottic airway device. It is good practice to test the correct assembly and functioning of the facial nerve

© Hodder Arnold / Scott-Brown 7E

Figure 40.4 A peripheral nerve stimulator. This passes a supramaximal (>50 mA) stimulus transcutaneously over the desired motor nerve, typically the ulnar nerve at the wrist, in order to assess the degree of neuromuscular block.

monitoring system before surgery by using the peripheral nerve stimulator. A short burst of tetanic stimulation applied over the facial nerve in front of the ear should produce visible contractions of the muscles and both visual and audible alerts from the monitor.

Postoperative plan

After some major operations of the head and neck (for example for tumour) involving free flap transfer, it is conventional for the postoperative plan to include admission to an intensive care unit for a period of artificial ventilation, which itself would require the presence of a tracheal tube. This plan might also be necessary if the patient has certain medical conditions (for example poor lung function).

KEY POINTS

- Anaesthesia and loss of consciousness result in reduced tone in the pharyngeal dilators and posterior displacement of the tongue.
- The oropharynx behaves as a Starling resistor: airflow is critically dependent on pharyngeal tone and transmural pressure.
- Maintaining the airway manually with a simple bag and mask is an important clinical skill.

CONDUCT OF ANAESTHESIA: PRINCIPLES GUIDING INDUCTION OF ANAESTHESIA

Preoxygenation

It is usual to allow a patient to breathe 100 percent oxygen via a face mask for a period of approximately two

to three minutes before the induction of anaesthesia. This process is known as preoxygenation and has a number of theoretical and real advantages. Perhaps counter-intuitively, breathing 100 percent oxygen in this way does not increase the oxygen content of the blood at all. This is because, for most patients, the arterial blood is almost fully saturated with oxygen even when breathing room air, so breathing oxygen cannot really improve on this. The purpose of this manoeuvre is rather to 'de-nitrogenate' the gas within the lungs. This increases the mass of oxygen within the alveolar compartment, which serves as a reservoir during a subsequent apnoea, and markedly delays the rate of desaturation during this period. An alternative technique for preoxygenation is to allow the patient to take three successive vital capacity breaths of 100 percent oxygen. For a resting lung volume of 2 L, and tidal breaths of 2 L, the alveolar oxygen concentration should rise from 16 percent on breath zero, to approximately 60 percent on breath one, 80 percent on breath two and 90 percent on breath three.^{5,6}

Intravenous induction

Perhaps the commonest mode of induction of anaesthesia is by i.v. injection (using one of the drugs listed in the above section, but most commonly probably propofol). This route rapidly induces anaesthesia. The advantage of this is that there is little or no 'stage of hyperexcitability'. This is a stage just before deep anaesthesia is attained, in which the patient may be paradoxically excitable and there is tongue-biting, vomiting and laryngeal spasm (see below under Inhalational induction). The aim is to titrate the intravenous administration of drug, slowly, according to the observed effect. Injudicious dosing of intravenous induction agents invariably causes loss of spontaneous ventilation, so at least for a period of time after induction (and for longer if neuromuscular blocking drugs are used) the anaesthetist must be confident of maintaining ventilation, using any or all of the means described above. If, therefore, there is any doubt on the part of the anaesthetist that s/he is able to maintain ventilation, then even the most carefully administered i.v. induction is probably not the safest means of inducing anaesthesia. The details and nature of these doubts (i.e. the ability to predict a patient who is difficult to intubate or ventilate) are discussed in Chapter 39, Recognition and management of the difficult airway.

If the use of neuromuscular blocking drugs is planned, it is important that the anaesthetist is satisfied that s/he can, if necessary, ventilate the patient with a bag and mask before such drugs are given. The precaution ensures that if for some reason the trachea cannot be intubated, then ventilation can at least be achieved with a bag and mask until spontaneous ventilation resumes.

Rapid sequence induction

This is a special form of i.v. induction that is employed to secure the airway with a tracheal tube, and so protect it from soiling, as quickly as possible. It is particularly indicated in emergency surgery where a patient may have a full stomach or a hiatus hernia with active reflux. It may also be considered where there is bleeding (as in post-tonsillectomy bleeding). In a rapid sequence induction we appear to break all the rules detailed above. Here, the induction is not slow, nor the dose titrated to effect so as to minimize the risk of apnoea, airway collapse and obstruction, but rather, a predetermined dose of i.v. agent is given rapidly as a bolus.

The muscle relaxant rule is also broken. In the rapid sequence induction we do not test our ability to ventilate the patient with a bag and mask before given neuromuscular blockers, but rather, give a dose of suxamethonium (or other rapidly acting drug) immediately following injection of the induction agent. This adds an extra burden of responsibility on the anaesthetist to be able to intubate the trachea, since we have chosen to neglect our 'escape plan'.

As soon as consciousness is seen to fall, the anaesthetic assistant applies 'cricoid pressure' to the larynx. Empirically, it is found that if a force of 40 N (4 kg weight) is applied to the cricoid cartilage using the finger and thumb, the posterior part of the cricoid cartilage will compress the oesophagus posteriorly against the C6 cervical vertebral body and so prevent passive spillage of gastric contents. Laryngoscopy and intubation are now undertaken in the usual manner.

Inhalational induction

An alternative means of inducing anaesthesia is by inhalational induction, using one of the vapours discussed above (most commonly either sevoflurane or halothane). Anaesthesia in children, who may be frightened of intravenous cannulation, is often induced in this manner. Historically, this was the first method of induction. One advantage of the technique is that it is theoretically a 'controlled' means of induction. If, during the course of inhalational induction, the patient's upper airway collapses and the patient's breathing becomes obstructed, then no further anaesthetic vapour can enter the lungs. The patient begins to wake up and thereby the upper airway tone and breathing are restored. For this reason, it has been advocated as the technique of choice in a case of upper airway obstruction and stridor (for example due to supraglottic tumour). Unlike an i.v. induction, therefore, inhalational induction may be used even when the anaesthetist has doubts about the ability to intubate the trachea or maintain ventilation. However, there are some practical disadvantages. First, because

induction is slow, there is a danger that the stage of excitability is prolonged. Second, should collapse of the upper airway occur during inhalational induction then not only anaesthetic vapour, but also oxygen is prevented from reaching the lungs. Thus, inhalational induction may not be as safe or controlled as may be claimed.

Induction after securing the airway

Certain patients, especially those whose tracheas are predicted to be difficult to intubate, are subjected to techniques that achieve tracheal intubation with the patient awake or sedated, with anaesthetic induction occurring only after the airway is secured. These methods are discussed further in Chapter 39, Recognition and management of the difficult airway. The methods may also include planned awake tracheostomy under local anaesthesia.

MONITORING IN ANAESTHESIA

Derived from the Latin *monere* – to warn, monitoring is used to describe measurements whose prime purpose is to 'warn' of imminent (possibly injurious) events, and allow action to be taken to avoid them, or moderate their effect. The Association of Anaesthetists of Great Britain and Ireland publishes guidelines for minimum monitoring standards, and these are reviewed from time to time. Undoubtedly, the most important 'monitor' is the very presence of an anaesthetist throughout the duration of anaesthesia who can synthesize information derived from clinical observation, and specialized devices.

Basic intraoperative monitoring

ECG

Continuous single-lead ECG recording is universally used. Electrical activity of the heart gives no information about pump function and circulation. Its purpose is to detect the development of dysrhythmias and/or myocardial ischaemia.

Lead II configuration is best for rhythm disturbances (AF, heart block, asystole, VT, VF) since this lead shows the presence (or absence) of P waves best. The CM₅ configuration is best for detecting myocardial ischaemia, (ST depression, T wave inversion) (see **Figure 40.5**).

PULSE OXIMETRY

These devices shine red light through an extremity, usually a finger, and measure the absorbance of this transmitted light by substances in its path. Clearly, there will be a number of substances which absorb and/or

Figure 40.5 (a) For standard lead connection, the right arm lead is placed on the right shoulder, the left arm lead on the left shoulder, and the left leg lead is placed centrally to form an equilateral triangle. Selection of 'lead II' on the monitor will connect leads RA to the negative terminal and LL to the positive terminal. Lead LA acts as an earth lead. (b) For CM₅ configuration, lead RA is placed on the central manubrium and lead LA at the V5 position in the anterior axillary line. The monitor is set to display 'lead I', which connects RA to the negative terminal and LA to the positive terminal. Lead LL is earth/ground/indifferent and its placement is not critical.

scatter this light energy, including arterial haemoglobin, venous haemoglobin, skin, bone and nail-bed. However, in addition to the background absorbance, there will be a component that varies throughout the cardiac cycle, and

this pulsatile absorbance is due to the added volume of arterial blood which enters during (or shortly after) systole. If this pulsatile signal is subtracted from the background signal we achieve an arterial absorbance signal that is wholly accounted for by the composition of arterial blood. The red light comprises two different wavelengths and these are absorbed by deoxygenated and oxygenated haemoglobin to different degrees. The relative absorbances of these wavelengths are used to calculate the proportions of oxygenated and deoxygenated haemoglobin, yielding a percentage SpO₂.

The pulse oximeter monitors oxygenation but **not** ventilation. This is an extremely important concept when considering high-risk patients nursed on the ward and recovery area. Patients breathing supplemental oxygen may still be pink, despite being virtually apnoeic (i.e. imminent respiratory arrest). Pulse oximeters must not be relied upon to monitor the adequacy of ventilation in patients who are at risk of respiratory depression or obstruction.

In addition, pulse plethysmography (the pulsatile waveform display shown on the pulse oximeter) gives a beat-to-beat indication of circulation, which is the electronic equivalent of keeping one's finger on the pulse at all times. This has become an invaluable tool.

BLOOD PRESSURE

Automatic noninvasive blood pressure

Automatic noninvasive blood pressure (NIBP) uses the principle of oscillotonometry applied to an inflatable cuff around the arm. This principle differs from the more familiar auscultatory method. The mean blood pressure measured by oscillotonometry is reasonably accurate. Systolic and particularly the diastolic values are less so. These automatic NIBP devices have gained widespread acceptance because they are safe and easy to use. They can be set to take measurements every few minutes and produce a printed chart, which is useful for detecting trends in theatre or the high dependency area.

NIBP measurement has a number of disadvantages. Firstly, its readings, even if taken frequently, are 'intermittent' and so do not allow one to detect sudden circulatory collapse. NIBP measurements tends to overestimate low pressures, and underestimate high pressures. It is often impossible to get any reading from patients who are 'shocked' and peripherally shut down.

Invasive monitoring of blood pressure

Invasive monitoring of blood pressure (IBP) can be measured by siting a cannula in a suitable artery, usually the radial. This has the advantage of allowing beat-to-beat blood pressure measurement, which allows extremely rapid changes to be detected almost in real time. The IBP monitor allows the arterial 'waveform' to be displayed on screen. The morphology of this waveform

(e.g. the rate of upstroke, pulse pressure, presence 'pulsus paradoxus' with respiration) provides useful information on circulatory and vasotonic status. Having an arterial cannula *in situ* also permits easy and regular blood gas sampling. IBP measurements are reliable and accurate in both high and low pressure states. Disadvantages are few, but include the fact that siting such cannulae can be fiddly, and the disposables are relatively expensive. There is a very small risk of thrombosis, distal ischaemia and infection.

GAS ANALYSIS

Inspired oxygen fraction (F_{iO_2})

It is axiomatic that oxygen is vital for safe anaesthesia. However, since it is odourless and colourless it is not straightforward to know how much is being given to a patient, or more worryingly, whether any is being given at all! Deaths still occur due to administration of gas devoid of oxygen, either by inadvertently giving pure nitrous oxide or carbon dioxide, or as a result of an error in gas pipeline connections. It is therefore vital that the labelled identity of the gas in a cylinder or pipeline is not relied upon, but that the composition of gases as they leave the anaesthetic machine and enter the patient's airway is monitored. This is usually carried out by means of continuous aspiration of a sample of gas from the airway into a rapid gas analyser which can display the concentration of inspired and expired oxygen breath-by-breath. Most analysers are also capable of monitoring other gas, such as CO_2 and anaesthetic gases and vapours.

Inspired/end-tidal anaesthetic agent concentration

By sampling the concentration (or partial pressure) of anaesthetic vapours in the expired breath, one can estimate the anaesthetic partial pressure in the alveolar gas and hence the arterial blood and brain. This is a very reliable way of monitoring anaesthetic depth because the dose-response curves (or more accurately the partial pressure-response curves) for these agents show very little interindividual variation. So, for example, if the end-tidal concentration of isoflurane is 1 percent, we can be extremely confident that for all patients, anaesthetic depth is adequate and there will be no danger of 'conscious awareness'.

Inspired and expired PCO_2

Inspired CO_2 should be zero or near zero. Rising inspired CO_2 concentrations indicate that the patient is rebreathing exhaled breath and this usually results from a faulty breathing circuit or inadequate gas supply from the anaesthetic machine.

Expired PCO_2 , and its waveform, is one of the most important monitors in anaesthesia. The term 'end-tidal' refers to the concentration at the very end of expiration

and this is taken to represent alveolar gas. The 'capnogram' (a graphical representation of expired PCO_2 versus time) provides an enormous amount of information on cardiorespiratory function. It is one of the earliest and most robust indicators of whether the trachea or oesophagus has been intubated. The presence of expired CO_2 and a normal 'alveolar waveform' definitively confirms endotracheal placement. Likewise, the absence of an alveolar waveform is strongly suggestive of oesophageal intubation.

The end-tidal PCO_2 is useful to confirm that alveolar ventilation is adequate. Hypoventilation and hyperventilation result in hypercapnia and hypocapnia, respectively. Clues to a number of other cardiopulmonary abnormalities can be gained from capnography, such as falling cardiac output, pulmonary embolus, V/Q maldistribution, the patient 'fighting' the ventilator. See example capnograms in **Figure 40.6**.

AIRWAY PRESSURE, TIDAL VOLUME

If patients are ventilated mechanically, the ventilator provides information on airway pressure and expired volume. Pressure is required to pass a volume of gas into the lungs. Two separate processes contribute to this pressure:

1. the compliance (or elastance) of the lung (the springiness of the spring);
2. the resistance to airflow (the narrowness of the tubes).

The compliance of the lungs is not usually a problem in most theatre cases (cf. ITU cases). Sudden changes in airway pressure usually indicate sudden changes in resistance (for example, sudden onset of bronchospasm in anaphylaxis, or kinking of the endotracheal tube by a Boyle Davis gag).

TEMPERATURE

Patients tend to get cold during surgery. This is because of:

- heat at loss to the environment (cold theatre, naked body, exposed body cavities);
- altered homeothermic mechanisms under anaesthesia.

This is bad for a number of practical and theoretical reasons. Hypothermia delays wound healing, depresses immunity, adversely affects skin integrity (so prone to pressure sores) and adversely affects coagulation.

Temperature is usually measured with an oro- or nasopharyngeal thermister. Rectal and intravascular varieties also exist. Our aim is to maintain normothermia by means of warm air convection blankets (e.g. Bair-HuggerTM) and by using an intravenous fluid warmer if the need for large volumes of fluid is anticipated.

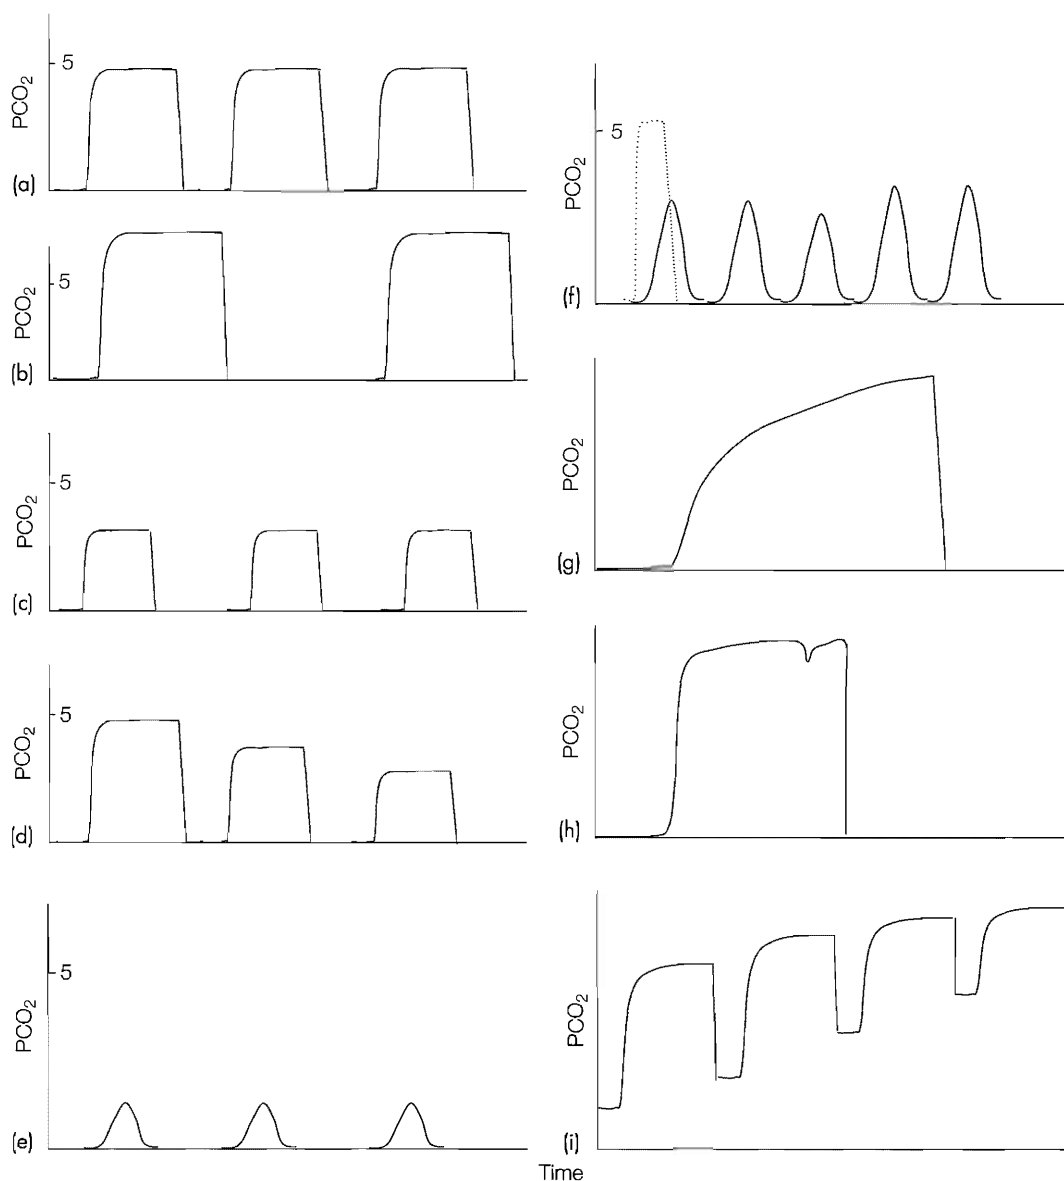

Figure 40.6 Example capnograms: (a) Normal capnogram series. Note: regularity of ventilatory cycle, flat alveolar plateaux, normal PACO₂ value, zero inspired PCO₂. (b) Hypoventilation. Shape of capnogram is normal, and alveolar plateau preserved, so airway flow must be normal. The likely cause is bradypnoea due to opiates. (c) Hyperventilation. Note that respiratory rate is normal so it is likely that the patient is being overventilated (tidal volume too great). Another rarer cause would be systemic shock with poor venous return. (d) Sudden fall in PCO₂ despite no change in ventilation. Causes: Pulmonary embolus (clot or air); circulatory arrest. (e) Loss of normal morphology. Small blips indicate insufficient alveolar gas is making it as far as the sample probe (at the lips). This is either because the tidal volume is very small (only just exceeding the dead space), or there is some upper airway obstruction which is physically hindering gas efflux on the final part of its journey from larynx to lips. In the case of ventilation via a face mask, this could indicate air leak from a poor seal, i.e. ventilation may be normal, but alveolar gas is not sampled properly because of the poor face mask seal. (f) Tachypnia. Rapid respiration is normal in babies. In adults, it may indicate inadequate anaesthesia or analgesia. In this example, the 'response time' of the analyser is not rapid enough to measure the true capnogram at this respiratory rate, so it appears as a series of rapid blips, the peaks of which do not represent true capnogram (dotted). (g) V/Q mismatch/lower airway obstruction. Note the sloping alveolar 'plateau'. Alveolar gas is not homogeneous. Low-resistance units, by definition, are well ventilated and have a low PCO₂, and because they are low-resistance, they empty first. High resistance units are poorly ventilated and have a high PCO₂. Because they are slow to empty, they dominate the latter part of expiration. This is classically seen in COAD and asthma. (h) 'Curare notch'. The notch in the alveolar plateau indicates that a patient may be trying to breathe in at this point (i.e. to fight against the ventilator). It usually means that the muscle relaxant is starting to wear off, this should be checked with the peripheral nerve stimulator before giving further doses. (i) Rebreathing/inadequate fresh gas supply. Here, the inspired PCO₂ is not zero. Some degree of 'rebreathing' is occurring as breathing in and out of a paper bag. The usual reason is failure of the gas supply from the anaesthetic machine to the breathing circuit. The patient's expired gas is not washed away by fresh gas, and so it ends up being rebreathed at the next inspiration.

CENTRAL VENOUS PRESSURE/PULMONARY ARTERY WEDGE PRESSURE/CARDIAC OUTPUT/TRANSOESOPHAGEAL ECHOCARDIOGRAPHY

This is **not** routine monitoring, but is used in situations where indicated either by:

- the patient's preoperative medical condition, e.g. left ventricular failure, sepsis;
- the surgery is likely to produce significant deviations in these parameters, e.g. large blood loss or compression of the mediastinum and great vessels.

The aim is to detect and correct changes in left and/or right ventricular preload, afterload or contractility indicated by changes in venous and pulmonary pressures, arterial pressure and cardiac output. Transoesophageal echocardiography (TOE) is particularly useful as it provides information on ventricular volume rather than pressure.

MONITORING OF NEUROMUSCULAR FUNCTION

The problems of neuromuscular blockade in the context of facial nerve monitoring in middle ear and parotid surgery has been discussed.

In general, the anaesthetist monitors the adequacy or completeness of neuromuscular blockade by means of a peripheral nerve stimulator. This comprises two adhesive electrodes placed over a convenient peripheral nerve (usually the ulnar) by which current pulses of around 50 mA are passed. These pulses provoke a visible, palpable and unfatigable twitch in the relevant muscles in the unparalysed patient. In the completely paralysed patient, no twitches are palpable. For degrees of paralysis between these extremes, a reduction in twitch amplitude (relative to the unparalysed twitch) is observed and, more particularly, a diminution in twitch amplitude with each successive impulse is seen, which is characteristic of the nondepolarizing (curare-like) neuromuscular blockers. It is important to remember that the ability to elicit palpable twitches is a crude test of neuromuscular function, in contrast to the facial nerve monitor used by the ENT surgeon, which detects microvolts of EMG activity, rather than gross movement. It is possible for patients to be moderately but adequately blocked from the anaesthetic perspective, but satisfactorily unblocked from the perspective of facial nerve monitoring. The important point here is that if this approach is used, the surgeon, as well as the anaesthetist, needs to be aware of it.

INDICES OF ANAESTHETIC DEPTH: EEG/AEP/BIS

A number of devices that measure and process EEG signals are available for estimating anaesthetic depth during surgery. In addition, auditory evoked potentials can be used since increasing anaesthetic depth increases the latency and reduces the amplitude of the early cortical responses. Knowledge of anaesthetic depth is important

for clinical and medico-legal purposes. For patients breathing spontaneously, i.e. not paralysed, 'awareness' under anaesthesia is very unlikely because if such patients became 'light', they would indicate this by moving or coughing, long before awareness supervened. In paralysed patients however, such early warning signs are absent. This is not routine monitoring.

ANAESTHETIC TECHNIQUE AND PRINCIPLES FOR SPECIFIC ENT OPERATIONS

The above sections indicate the broad principles used to determine choice of anaesthetic drugs, airway device and mode of induction. We now turn to some specific operations in ENT surgery and outline the relevant anaesthetic considerations.

Tonsillectomy and adenoidectomy

The most common reason for this operation is chronic or recurrent infection, and it is usually carried out in children. Thus, the incidence of upper respiratory tract infection on day of surgery is common, often requiring postponement of the operation. Extremely anxious children may need sedation on the ward using oral midazolam 0.5–1 mg/kg, and may need inhalational induction of anaesthesia, but this is rare. Most children, however, accept local anaesthetic cream (EMLA or Ametop) which facilitates i.v. cannulation and induction. It is usual for parents to be present during induction. Other reasons for the operation include: as part of treatment for sleep apnoea syndrome or snoring; excision biopsy for suspected malignancy; or peritonsillar abscess. These operations are usually performed in adults.

AIRWAY MANAGEMENT

Most anaesthetists would probably choose to intubate the trachea because this secures the airway and facilitates ventilation more definitively. Commonly a 'preformed' tracheal tube is used, such as an RAE tube (**Figure 40.3**). This tube is designed such that its outside end (which connects to the breathing circuit) points 'south' naturally (i.e. sits under the Boyle Davies gag) without having to be bent. The act of bending tubes usually results in kinking and obstruction. An alternative tube is a reinforced tube, whose shaft is flexible and kink resistant. An integral metallic spiral provides this protection from external compression and kinking (**Figure 40.3**). Since tonsillectomy is mostly carried out in children, uncuffed or 'plain' tracheal tubes are mostly used. This means that the lower airway is not definitively sealed and protected from soiling by blood. In addition, the laryngeal inlet cannot easily be sealed with a throat-pack (as would be done in

other types of surgery) because this would most likely obscure the surgical field. The anaesthetist therefore relies on the surgeon to prevent blood from entering the larynx by careful haemostasis and use of suction.

It is now relatively common for the flexible, reinforced version of the LMA to be used, as it is suggested that the inflated cuff, which sits around the outside of the laryngeal inlet, acts as an effective barrier to lung soiling. The reinforced LMA has a narrower tube portion which is not only kink resistant and sits under the Boyle Davies gag, but also obscures the surgical view less than the standard LMA. Whichever airway device is used, care should be taken that it remains patent during surgery, especially at the point where the Boyle Davis gag is placed (Figure 40.7).

MAINTENANCE

The traditional technique, with a number of advantages, is to use a volatile anaesthetic agent and to allow the patient to breathe spontaneously. In this technique, after induction of anaesthesia, a short-acting muscle relaxant such as suxamethonium or mivacurium is used to facilitate tracheal intubation. Spontaneous respiration will soon resume and the patient allowed to breathe a mixture of oxygen and nitrous oxide with the addition of a volatile agent such as isoflurane or sevoflurane. As discussed above, a relatively deep plane of anaesthesia will be required for the patient to tolerate the tracheal tube without coughing. Analgesia may be provided by an opioid, and titrated such that respiration is not depressed.

EXTUBATION/RECOVERY

At the end of the case, the laryngeal inlet is examined with the aid of a Macintosh laryngoscope and gently suctioned to confirm that haemostasis is secure. The patient is

positioned in the lateral position, with a pillow placed under the upper chest and the head tilted down so that any blood or secretions will drain without soiling the airway. The patient, still breathing spontaneously, is then extubated at the peak of inspiration, still under a 'deep' plane of anaesthesia. The subsequent expiration should clear any small quantity of blood or secretions from the laryngeal inlet, and respiration should continue unimpeded and without coughing. The patient is then transferred to the recovery ward where, with modern fast onset/offset agents, the volatile agent will soon be washed-out, and consciousness return.

THE POSTOPERATIVE BLEEDING TONSIL

This is a serious complication. Anaesthesia and surgery may be necessary after appropriate fluid and volume resuscitation. The patient (especially a child) may have swallowed most of the blood and must be treated as a high risk for regurgitation and aspiration. At the same time, the trachea may be difficult to intubate due to the presence of blood in the oropharynx and oedema from the recent surgery. The options for anaesthetic induction are either a standard 'rapid sequence' intravenous technique (probably favoured by most anaesthetists), or a careful inhalational induction with the patient in the head down, lateral position. There must be good communication between the teams: the surgeon must be prepared to establish an emergency surgical airway or tracheostomy should tracheal intubation fail.

Ear surgery

Surgery on the external ear is performed for a variety of reconstructive or cosmetic reasons. Surgery on the middle ear is performed to restore hearing, eliminate infection, treat cholesteatoma or, rarely, for neoplasm.

Figure 40.7 The relative positions of: (a) the tracheal tube; and (b) the tonsillectomy (Boyle Davis) gag. Note how the blade retracts the tongue and the tube upwards.

The main anaesthetic implication is that the head must be turned so that the ear on which the operation occurs is turned upward. It is one instance in ENT surgery when, strictly speaking, the airway is not ‘shared’ and so anaesthetic considerations, rather than surgical considerations, predominate in choice of airway or anaesthetic drugs. However, where tympanoplasty, tympanomeatal flaps, stapedotomy or stapedectomy is performed, it is advisable to avoid nitrous oxide. Nitrous oxide (due to its relative solubility) enters the middle ear cavity at a rate faster than nitrogen (the ambient gas in the air) leaves the space: consequently, there is a rise in middle ear pressure which can displace the structures being operated on. Myringotomy (grommet) surgery, is usually a very short operation in children and any suitable anaesthetic technique may be employed.

More invasive operations of the ear include exploratory middle ear surgery and mastoidectomy. The surgical approach is often by a post-auricular approach, through the mastoid. The main consideration is that the facial nerve needs to be monitored during surgery (see above under Monitoring of neuromuscular function).

HYPOTENSIVE ANAESTHESIA

In certain operations, notably major ear surgery, special techniques are employed to improve the view of the surgical field by minimizing bleeding. These techniques have become collectively known as ‘hypotensive anaesthesia’ although they comprise a number of other approaches in addition to hypotension.

Blood in the surgical field may arise from arterial, capillary or venous bleeding. Arterial bleeding is directly proportional to mean arterial blood pressure (MABP), which is governed by the following relationship:

$$\begin{aligned} \text{MABP} &= \text{cardiac output} \times \text{peripheral vascular resistance} \\ &= (\text{stroke volume} \times \text{heart rate}) \times \text{peripheral vascular resistance} \end{aligned}$$

A reduction in stroke volume (via a reduction in contractility) and a reduction in heart rate can be achieved by β blockade. A reduction in peripheral

vascular resistance can be achieved (via vasodilatation) with alpha blocking drugs (such as phentolamine) or increased concentrations of volatile anaesthetic agents.

Capillary bleeding depends on local flow in the capillary bed, which in turn is dependent on upstream arterial pressure and downstream venous tone, in addition to local metabolic factors. Capillary bleeding can be moderated by the use of locally infiltrated adrenaline (although the systemic effects of this will transiently confound the anaesthetist’s attempts to control blood pressure) and by reduction in arterial and venous PCO_2 by hyperventilation.

A reduction in venous tone and backpressure will reduce both capillary and venous bleeding. Venous tone can be moderated by the use of intravenous nitrates, and positioning can reduce the hydrostatic venous pressure, for example a 25° head up tilt can be employed in middle ear surgery.

In young healthy patients, blood flow to vital organs such as the brain, kidney and heart is regulated such that it remains constant despite variations in perfusion pressure. This autoregulation occurs within a mean arterial pressure range of 60–160 mmHg. At pressures below 60 mmHg mean, blood flow becomes ‘pressure dependent’ and will diminish with diminishing pressure, (see **Figure 40.8**).

For such patients, MABP may safely be lowered to 60 mmHg without diminution of vital organ blood flow. Even at pressures lower still, a modest reduction in organ blood flow is unlikely to be clinically significant since there is little metabolic demand under these basal conditions.

However, in elderly patients, and particularly those with systemic hypertension or coronary artery disease, the imposition of deliberate hypotension should not be undertaken lightly. In systemic hypertension, the normal autoregulation curve (shown in **Figure 40.8**) is shifted to the right, and so even moderate degrees of induced hypotension may produce pressure-dependent flow and reduce vital organ perfusion. The ‘re-setting’ of these autoregulatory mechanisms is time-dependent and may take several weeks to normalize after a hypertensive

Figure 40.8 Autoregulation curve.

patient is started on antihypertensive therapy. It is for this reason that it is unwise to embark on anaesthesia in hypertensive patients, even though we can quite easily and quickly achieve systolic and diastolic blood-pressure values that are in the normal range. The second group of patients in whom induced hypotension should be effected with caution are those with coronary or cerebrovascular disease. The arterial pressure just downstream of a stenosis may be 20 or more mmHg lower than the upstream (or systemic) arterial pressure. So, whilst a mean systemic pressure of 60 mmHg may be adequate for the majority of an arteriopathic patient's organ systems, such a pressure may only generate 40 mmHg of pressure downstream of a fixed stenosis, thus producing a diminished and pressure-dependent flow with a risk of myocardial ischaemia or cerebral thrombosis.⁷

SALIVARY GLAND SURGERY

Parotidectomy and removal of submandibular gland may be performed for tumour, stone or chronic infection. Any suitable anaesthetic technique may be used, but the facial nerve may need to be monitored.

NASAL AND SINUS SURGERY

Nasal surgery is performed for cosmetic or functional restoration of the nasal airway, and includes operations such as septoplasty (operations to the nasal septum), rhinoplasty (operations to remodel the nasal contour), turbinectomy or these combined. Sinus surgery is performed to eliminate infection, polyps or neoplastic conditions of the sinuses, and the goal is to provide aeration of the sinuses so that secretion can drain adequately into the nasopharynx. The operations are usually performed in young adults.

Anaesthetic considerations for all these operations are similar. An oral (as opposed to nasal) airway device is necessary (usually a tracheal tube in combination with a gauze throat pack to collect any blood which trickles from the nose). Nasal bleeding is often minimized by surgical application of cocaine mixtures to the nose before the operation begins. At the end of surgery, the patient's nose is usually packed, so a good oral airway should be established to allow the patient to breathe spontaneously.

LARYNGEAL MICROSURGERY AND LARYNGOSCOPY

These operations are performed for diagnostic or therapeutic purposes and may be combined with an examination of the pharynx, oesophagus or bronchial tree. Often, lasers are used to treat isolated lesions of the larynx.

Because of the rigid nature of the laryngoscope, a small size (6 mm internal diameter or less) tracheal tube (a microlaryngeal tube) is commonly employed, and if lasers are to be used, an appropriate laser-resistant type is needed. This type of tracheal tube is sufficiently flexible and long that it does not interfere with the surgical field, although good communication is needed between surgeon and anaesthetist throughout the procedure. The operation is usually relatively short, but laryngospasm or postoperative airway obstruction due to oedema of the vocal cords may occur. The risk of this may be minimized if steroids (for example dexamethasone 8 mg intravenously) are used preoperatively.

LASER SURGERY

The use of laser, especially for laryngeal microsurgery, has become widespread. Lasers are also used for stapedectomy, tympanoplasty, turbinate surgery and oropharyngeal surgery. There are various types of laser (CO₂, Nd:Yag, KTP; all named after the source of substrate for the laser beam). It is important to know the general properties of the laser beam that is being used. The Nd:Yag laser (yttrium-aluminium-garnet) was introduced in the 1980s, and its main advantage over CO₂ laser is that it can be delivered by means of an easily handled flexible fiberoptic light cable. It has more coagulative but less cutting ability than a CO₂ laser. The KTP laser is a variant of the Nd:Yag, in which the laser beam is passed through a potassium titanyl phosphate crystal. Lasers can produce either a parallel or divergent beam. Parallel beams impart much greater power densities to the tissues they strike than divergent beams. The greatest concern during use of lasers is the possibility of uncontrolled combustion of either tissues or extraneous materials (including airway devices) if accidentally struck for prolonged periods by the laser beam. A fire in the patient's airway is serious and is often fatal. The steps shown under Best clinical practice are reasonable precautions to minimize this risk.⁸

Bronchoscopy

Rigid bronchoscopy is performed for a variety of reasons, including inhaled foreign body, diagnosis of endobronchial lesions, and staging of disease prior to pulmonary resection. The type of patient who presents for this procedure can therefore be extremely variable, from a small child to an elderly smoker with severe lung disease. An important anaesthetic consideration is that the large rigid bronchoscope competes for space with anaesthetic devices within the trachea itself (**Figure 40.9**). Pulmonary ventilation needs to continue during the procedure and this can be achieved in the following ways:

- Using a small tracheal tube, though the risk is that the bronchoscope may dislodge this.

© Hodder Arnold / Scott-Brown 7E

Figure 40.9 A Sanders injector and rigid bronchoscope. High-pressure oxygen is fed from the regulator to a jet orifice, which clips or screws loosely onto a sideport of the rigid bronchoscope. The jet is controlled by the hand trigger. Note that the connection of the jet orifice to the sideport is not sealed and there is considerable leak so the patient is not exposed to the full pressure of the injector, but rather room air is entrained into the scope by the jetting oxygen. Note also how the conventional anaesthetic circuit can also be attached (without leak) to the sideport to allow conventional ventilation (although the leak at the level of the bronchoscope and the vocal cords may make ventilation in this way difficult).

- Using the technique of 'apnoeic oxygenation'. This involves oxygenating the patient's lungs with 100 percent oxygen until the lung volume is depleted of nitrogen and effectively full of oxygen and no other gas. All airway devices are removed save for a small catheter, which insufflates oxygen into the oropharynx. The surgeon is then allowed to proceed with bronchoscopy with the patient apnoeic. Because of the relatively low rate of basal oxygen consumption, and the continued minimal delivery of oxygen via the catheter, it is theoretically possible to continue oxygenation indefinitely. However, the duration of the procedure is limited by the accumulation of carbon dioxide (active pulmonary ventilation is necessary for its removal). This accumulates in the patient's blood at a rate of approximately 0.5 kPa per minute, which limits the safe time of apnoea to approximately ten minutes.
- Employing a method known as 'jet ventilation' using a Sanders injector (**Figure 40.9**). This injector is essentially a pressure relief valve and tubing, one end of which is attached directly to the high pressure (4 bar) oxygen pressure supply on the anaesthetic machine. The other end of the tubing is attached to the rigid bronchoscope. Opening the injector blows oxygen at high pressure into the lungs and inflates them. Because of the high pressures involved, such injectors can be extremely dangerous to use without training. After injection of oxygen, sufficient time must then be allowed for air to leave the lungs (passive expiration).

- Some bronchoscopes have a side-port (Racine adaptor) which allows the standard anaesthetic/oxygen tubing to be attached: the anaesthetist can hand-ventilate the patient's lungs in a conventional manner using this attachment during bronchoscopy (**Figure 40.9**).

Since the anaesthetic management for rigid bronchoscopy is varied and relatively specialized, good communication between anaesthetist and surgeon is essential.

Laryngectomy

This is normally performed for tumour of the larynx. A total laryngectomy involves removal of all tissues from the vallecula (and sometimes base of tongue) to the second or third tracheal rings. Occasionally, the thyroid gland also needs to be removed. The pharynx is closed in a T-shape, and the trachea is brought out to the skin as an end-tracheostomy (so no special tube is required long term to maintain airway patency). There are variations of this operation. A supraglottic laryngectomy involves resection of all tissue from the base of tongue to the vocal cords (which are left intact). The strap muscles are also preserved. A temporary tracheostomy is required post-operatively. A hemilaryngectomy involves removal of the epiglottis and just one half of the larynx (including one true and false vocal cord).

The main anaesthetic considerations are usually:

- the preoperative state of the patient;
- tracheal intubation during anaesthetic induction;
- changes of airway device during surgery.

PREOPERATIVE PATIENT STATE

Laryngeal tumours commonly occur in elderly smokers, so there may be considerable coexistent cardiovascular and respiratory disease which the anaesthetist needs to manage during surgery. There may need to be a preoperative plan to optimize any coexistent medical conditions and additional monitoring (for example invasive arterial pressures and central venous monitoring) may be necessary during surgery. If lung function is particularly poor, the plan may include a period of elective postoperative ventilation in intensive care.

TRACHEAL INTUBATION

The presence of a laryngeal tumour may make conventional tracheal intubation difficult, and specialized techniques may be necessary (for example awake intubation) during induction of anaesthesia. These are further discussed in Chapter 39, Recognition and management of the difficult airway.

AIRWAY DURING SURGERY

The operation might begin with the patient's trachea intubated with a standard (Magill) orotracheal tube. As surgery proceeds, this may (for reasons of surgical access) need to be exchanged for a tracheal tube which is inserted directly percutaneously into the trachea and shaped to lie against the neck, pointing caudally (for example Montandi tube, reinforced flexible tube or RAE tube). Finally, as the permanent end-tracheostomy is fashioned, all tracheal tubes will be removed. Thus, the anaesthetist needs to have ready a number of sterile airway devices, sterile connectors and tubing which often need to be sited directly by the surgeon. Close communication is clearly necessary.⁹

KEY POINTS

- Anaesthesia for ENT surgery epitomizes the quintessentially anaesthetic 'art' of airway mastery.
- It requires a unique dialogue between surgeon and anaesthetist who share the same territory. As such it requires, perhaps more than any other branch of surgery, an understanding of, and respect for each others contribution towards a common end.

Tonsillectomy and adenoidectomy

- The airway may be maintained by either insertion of a tracheal tube, or with a laryngeal mask. The choice is down to operator preference.

- The return to theatre of a bleeding tonsil poses special problems for the anaesthetist due to the probability of a full stomach and obscured laryngoscopy.

Ear surgery

- Moderate hypotension may help to reduce bleeding in the surgical field.
- It requires a multimodal approach rather than the use of a single agent or technique.
- It should be used with caution in patients with uncontrolled hypertension, cerebrovascular or ischaemic heart disease.

Best clinical practice

Laser surgery

- ✓ The surgeon should exercise caution and avoid any direct strikes to the airway device. This risk might be minimized during oral surgery if a Boyle Davis gag without the Doughty modification is used, thus protecting the shaft of most airway devices. If the Doughty modification is used, then the shaft of the airway device might be protected using damp gauzes or swabs.
- ✓ The minimum power output of the laser should be used and the duration of laser strike limited. It has been found that the risk of combustion increases with duration of strike at the same power.
- ✓ Both oxygen and nitrous oxide support combustion. Ideally, a mixture of oxygen (perhaps limited to no greater than 30 percent) mixed with air should be used to ventilate the patient's lungs during anaesthesia, to minimize the risk of combustion.
- ✓ Cuffs of tracheal and SAD devices are more vulnerable to laser strike than are the shafts of these devices. Therefore, the cuffs should be filled with saline (or coloured water) rather than air. This protects them, to some extent, from combustion with laser strike; it slows any deflation of the cuff after strike; it aids, to some extent, in preventing spread of any fire; and the leak of fluid allows the surgeon to see that the cuff has been ruptured.

Deficiencies in current practice and areas for future research

The scope for research in anaesthesia is huge. At the most fundamental level, it is not known how anaesthetic drugs induce unconsciousness and research in this field will span neurophysiology as well as, perhaps,

psychology. Of more immediate relevance to anaesthesia in the context of head and neck surgery are the following areas:

- Drug developments
 - In particular, the search continues for anaesthetic drugs that have minimal effects on the cardiovascular and respiratory systems. It is expected that such drugs will possess a better safety profile, with fewer adverse cardio-respiratory side effects.
 - The search for drugs that minimize – or treat – postoperative nausea and vomiting is also important. While not addressing life-saving issues, this area of research certainly aims to improve quality of life, and also costs, since delayed discharge from hospital due to nausea/vomiting is an important cause of additional costs to a healthcare organization.
- Airway management. Current techniques for airway management in those patients who present particular difficulties (especially common in head and neck surgery) involve relatively expensive items of equipment such as fiberoptic endoscopes, and also require additional training in their use by experts who are proficient in managing these difficult cases. It would be desirable to introduce a technique – or equipment – which is both low-cost and which requires minimal expertise in its use to maintain an airway. However, developing such devices or techniques will require far more understanding of the reasons underlying the concept of the 'difficult airway' than we have at present.
- Reducing blood loss and blood replacement. Anaesthetic techniques that help minimize blood loss during surgery (such as 'hypotensive anaesthesia' in which the patient's blood pressure is held at low levels) require further research. This research also involves developments in more precise monitoring of

the circulation. Related to this are areas of research in artificial haemoglobins or haemoglobin substitutes designed to minimize the transfusion of blood and so reduce the attendant risks.

Specific surgical procedures	513		

INTRODUCTION

This chapter is intended to provide an overview of the principles of anaesthetic care for children in general, with specific reference to ear, nose and throat (ENT) surgery. The introductory section briefly deals with the organization of services for paediatric surgery and anaesthesia. This is followed by a consideration of preoperative factors, including physical assessment, preoperative fasting and premedication. The third section of the chapter addresses the equipment and skills necessary for the safe conduct of anaesthesia in children, with a particular emphasis on management of the airway. Induction of anaesthesia and physiological monitoring during anaesthesia are also covered in this section. The final section comprises an account of anaesthetic considerations and conduct for specific operative procedures commonly encountered in paediatric ENT surgery.

Ear, nose and throat surgery accounts for a significant percentage of all paediatric surgical procedures and provides the basis of many anaesthetists' experience with children. Many of these procedures are undertaken in centres where little or no other paediatric surgery is encountered. Whilst the majority of such operations are minor and of short duration, the nature of some ENT surgical procedures, particularly those involving the airway, require considerable expertise and experience. The development of cooperation and understanding between surgeon and anaesthetist is of enormous importance when undertaking such procedures.

Fundamental to the delivery of a safe, high-quality anaesthetic service for children is a suitably trained anaesthetist with continuing paediatric experience. Such an individual, however, must work in an environment with appropriate facilities and support if the reasonable expectations of children and their carers are to be met. The UK Department of Health defined the requirements for such a service in *The Welfare of Children and Young People in Hospital*.¹ There has been debate concerning who, where and what constitutes best practice in the delivery of surgical services for children, addressing such issues as training, ongoing experience and the merits of caring for children in a specialist paediatric centre as opposed to a general hospital environment.^{2, 3, 4} The majority of children presenting for surgical treatment in the UK have been cared for in the district hospital environment and there is no reason why most children should not be treated outside specialist centres if standards can be maintained.

The 1989 National Confidential Enquiry into Perioperative Deaths reviewed the surgical and anaesthetic care of children in hospital.⁵ The report highlighted the problems of 'occasional paediatric practice' and that the outcome of surgery and anaesthesia for children is related to experience. Numerous changes, which have required considerable reorganization in service delivery for children, have been recommended. It is increasingly the case that surgeons, anaesthetists and others are now working to defined values and standards and are organizing and auditing paediatric surgical services in a way that has led to a better defined and improved service for children.

PREOPERATIVE ASSESSMENT

Preoperative assessment for surgery involves an exchange of information between anaesthetist, child and carers that addresses three important issues vital to the conduct of a safe and satisfactory procedure. The first objective is to establish the nature of the procedure and to determine that the child is fit for surgery. Additionally, anatomical or physiological factors that may be specific to the condition to be treated or represent an unrelated disease process should be identified. Information obtained here will inform the development of the optimal anaesthetic care plan and may prompt further investigation or treatment before the procedure is undertaken. Thirdly, establishment of a rapport with children and their carers based on honesty and trust is vital to allay anxiety.

Psychological preparation for anaesthesia and surgery

For many children and their carers, the psychological disruption attendant upon a surgical procedure is at least as disturbing as the effects of the operation itself. Anaesthesia is particularly likely to contribute to emotional disturbance and so the conduct of pre-anaesthetic preparation is of great importance. Care should be taken to understand and address the concerns of both the child and their parents simply but truthfully. An understanding of age-specific responses to stress and the provision of a dedicated, child-friendly environment are important to consider when preparing children for surgery.

Day case surgery

The majority of minor ENT surgical procedures are undertaken on a day-stay basis, which affords an effective use of resources and has advantages for the child and their family. Pre-admission assessment of children, often nurse-led and employing questionnaire screening, speeds the admission process, limits wastage of operating time and reduces preventable cancellation on the day of surgery.

Physical examination

All children receive a full physical examination before anaesthesia and surgery, with emphasis placed on respiratory and cardiovascular systems. A careful assessment of the airway, including mouth opening, loose dentition and nasal obstruction is important to anticipate difficulties in airway management during anaesthesia.

Attention should also be paid to coexisting anomalies or disease that may require modifications of the

anaesthetic technique or particular precautions to be taken.

Respiratory assessment

Airway and respiratory complications are the most common causes of peri-anaesthetic morbidity in children. Children presenting for ENT surgical procedures frequently exhibit concurrent or associated respiratory disease, emphasizing the importance of thorough preoperative evaluation.

Healthy children, in particular infants and toddlers, have a significantly greater risk of respiratory complications than do healthy adults.⁶ This is predominantly related to maturational aspects of the respiratory system and the effects of anaesthesia on active mechanisms that help to maintain lung volume and functional residual capacity in infants and small children. In addition, stimulation of vagal airway receptors tends to increase the incidence of laryngospasm and apnoea in infants.

The inherent predisposition of small children to respiratory complications is compounded by the frequency of upper respiratory tract disturbances in the ENT surgical population and the decision to proceed with or defer surgery in a child with signs of an upper respiratory tract infection (URTI) presents a common dilemma. The features of URTI associated with anaesthetic complications may be difficult to define and the decision to proceed or not is often based on personal experience and a hierarchy of symptoms. Two recent studies^{7,8} have examined the incidence of and risk factors for adverse respiratory events in children with URTI. These studies suggest that many children with acute or recent URTI can undergo minor elective procedures such as myringotomy safely. The variables most likely to predict an adverse event are outlined in **Table 41.1**.

Asthma is common in childhood and there is a perception that the prevalence is increasing. Optimization of maintenance medication may be required prior to surgery but, in the absence of significant bronchospasm or intercurrent respiratory infection, most children can be safely managed with attention to the avoidance of anaesthetic agents likely to provoke histamine release.

Upper airway obstruction is frequent in paediatric ENT patients and evaluation of the cause and severity is important both in terms of airway management during anaesthesia and in determining the risk of airway difficulties in the postoperative period. Adenotonsillar hypertrophy is the most common cause of upper airway obstruction but others, notably congenital and acquired anomalies of the jaw, nasal and oral airways and larynx as well as craniofacial anomalies, particularly of the midface, are also encountered in this population. In addition, children with other conditions, such as Down's syndrome or neuromuscular disease, may develop airway

Table 41.1 Disease and anaesthetic factors likely to predict an adverse event in children with URTI.^{7,8}

Patient factors	Anaesthetic factors
Parental report of a 'cold'	Tracheal intubation versus face mask or LMA
Presence of a productive cough	Lack of anticholinesterase administration
Passive smoke exposure	Thiopentone or halothane induction versus propofol or sevoflurane
Presence of snoring	Surgery involving the airway
Presence of nasal congestion	

obstruction in the presence of relatively mild degrees of hypertrophy.

Although minor airway obstruction and benign snoring are common in children and do not usually pose particular risks, more severe airway obstruction may cause obstructive sleep apnoea syndrome (OSAS) and may predispose to significant airway compromise in the postoperative period. Preoperative OSAS, characterized by disturbed sleep with snoring, apnoeic pauses and hypoxia, in children undergoing adenotonsillectomy is a risk factor for postoperative respiratory compromise,^{9,10} and prediction of those most at risk is the subject of extensive studies.^{11,12,13,14}

Preoperative fasting

Preoperative fasting has long been considered essential for elective surgery. Prolonged fasting, however, does not reduce the aspiration risk during anaesthesia and current practice has focused on reduction of starvation times and a greater appreciation of other risk factors for regurgitation and aspiration of gastric contents.¹⁵ The current practice in most centres for elective surgery, summarized in **Table 41.2**, is based on ensuring minimal residual gastric volume at induction of anaesthesia and avoiding patient distress and potential under hydration associated with prolonged starvation.

This practice is supported by studies in children and infants^{16,17,18} and appears to improve the preoperative experience of children and parents.¹⁹ In children undergoing emergency procedures, however, a full six-hour fasting period may be considered necessary, unless the urgency of the surgery dictates otherwise and anaesthesia is conducted assuming that the child has a full stomach.

Premedication

Pharmacological premedication in paediatric practice remains a controversial subject. The routine use of premedicant schedules has largely been abandoned in favour of an individualized approach with specific goals in mind. Although the general trend has been a reduction in premedication and certainly in the use of

Table 41.2 Minimum preoperative fasting times in infants and children for elective surgery.

	Clear fluids	Breast milk	Formula or cow's milk	Solids
Children	2 hours	–	6 hours	6 hours
Infants	2 hours	4 hours	6 hours	6 hours

intramuscular agents, topical local anaesthetics, sedative agents and anticholinergics are still widely used.

The topical local anaesthetic agents EMLA cream²⁰ and Ametop gel²¹ are effective in reducing the pain of venepuncture and in facilitating intravenous induction. Although effective, in some children the anticipation of an unpleasant experience may outweigh the benefits afforded.

The value of sedative premedication is questionable for many children and is certainly no substitute for sympathetic psychological preparation. Historically, many classes of drugs have been used for this purpose but currently benzodiazepines and particularly Midazolam administered orally or, less frequently, intranasally, are the most popular agents.²² Midazolam affords anxiolysis and amnesia and its elimination half-life of two hours makes it suitable for use in day-case or inpatient procedures. Timing of premedication is important, maximal effect being within 30 minutes of oral administration.

Preoperative administration of anticholinergic agents, particularly Atropine, has long been considered best practice in paediatric anaesthesia, especially in infants. Newer anaesthetic agents and techniques have modified this approach and there has been a general decline in the use of anticholinergic premedication,^{23,24} although some still advocate its routine use.²⁵ Procedures involving the pharynx or airway and ophthalmic operations are particularly likely to provoke vagal reflexes and many anaesthetists continue to use anticholinergics in these cases.

There is an increasing trend in paediatric anaesthesia to prescribe simple analgesic or antiinflammatory drugs, such as paracetamol, preoperatively to children undergoing minor procedures. In appropriate dosage (30–40 mg/kg), this appears to be effective in reducing the use of postoperative opiate analgesia with its attendant problems of nausea and vomiting²⁶ and is safe in terms of residual gastric volume at induction of anaesthesia.²⁷

EQUIPMENT AND TECHNIQUES

Equipment for paediatric anaesthesia

Historically, anaesthetists dealing with children were faced with the task of adapting equipment designed for adult use and using their ingenuity to produce results that were at best mediocre by modern standards. Significant advances in technology and the understanding of paediatric physiology now make it unacceptable to consider anaesthesia for children without a full range of equipment designed specifically for that purpose. Most anaesthesia departments now have a designated ‘lead’ for paediatric anaesthesia with particular responsibility for the procurement and maintenance of appropriate equipment.

Paediatric breathing systems

The observations of Phillip Ayre²⁸ in 1937 on the effects of using a closed breathing system designed for adults in infants led him to develop the T-piece system with minimal dead space and resistance to breathing and a continuous supply of oxygen close to the airway. The Jackson Rees modification of this system²⁹ described in 1950 remains popular with many anaesthetists despite many subsequent advances (Figure 41.1).

The classification of anaesthetic breathing systems and an understanding of their functional characteristics^{30, 31} has allowed the development of a number of different systems appropriate for paediatric use.^{32, 33} Other considerations, such as reduction of atmospheric pollution by inhalational agents and the economic use of newer, expensive inhalation agents, have further influenced development.

Airway management equipment

Much of the morbidity in anaesthetized children is related to airway difficulties, and safe management of the airway

is, perhaps, the most important aspect of paediatric anaesthesia. This is particularly the case in many ENT procedures where surgery involves a ‘shared airway’ between surgeon and anaesthetist. Notwithstanding the huge range of airway devices available, the anaesthetist’s most important assets are sound basic airway management skills and an understanding of the anatomy and physiology of the paediatric airway. Equipment choices for airway maintenance during anaesthesia are a face mask with or without an oral or nasopharyngeal airway, a laryngeal mask airway, a tracheal tube or a more complex method such as tracheostomy.

Face masks are used during spontaneous breathing for short procedures, such as myringotomy and for pre-oxygenation and inhalational induction of anaesthesia. Ideally, they should be nonthreatening, easy to apply and achieve a good seal with minimal pressure on the face. Clear plastic face masks with cushioned rims are available in appropriate shapes and sizes for children of all ages and fulfil these requirements in all respects. Most of these are latex-free and some are available with ‘flavour’ impregnated rims, which may be helpful during inhalational induction.

The laryngeal mask airway (LMA)³⁴ introduced in the mid-1980s has greatly assisted in the management of both the routine and the difficult airway. Although originally developed for adults, LMAs are now available in sizes suitable for use in children of all ages, including neonates (Table 41.3).

Laryngeal masks are particularly useful in many ENT procedures, allowing adequate surgical access whilst avoiding intubation of the trachea. The reinforced LMA, which has a kink-resistant flexometallic oropharyngeal tube, is commonly used in head and neck surgery (Figure 41.2). As well as its extensive use in routine anaesthetic practice, the LMA is increasingly being used as an adjunct to fibroscopic examination and intubation of the paediatric airway.

Tracheal intubation remains the standard for airway maintenance during many procedures. The anatomical features of the child’s airway influencing tube selection are well known³⁶ and hinge on the nature of the cricoid ring. Generally, a tracheal tube of the largest possible

internal diameter should be chosen to minimize resistance to gas flow and avoid an excessive leak around the tube. It is important, however, to avoid inserting too large a tube, which may cause mucosal damage with the attendant risks of post-extubation airway difficulties.

Uncuffed, disposable polyvinyl chloride (PVC) tubes are available in a wide range of internal diameters and are commonly used in children under eight years of age. Although there is considerable individual variation, it is generally the case that a child's age, rather than height, weight or other characteristics, correlates best with the optimal tube diameter. Numerous formulae to help choose the correct diameter have been proposed of which the most often quoted (for uncuffed PVC tubes) is:³⁷

$$\begin{aligned} \text{Internal diameter (mm)} &= \frac{\text{Age (years)}}{3} \\ &+ 3.75 \text{ (for children under six years of age)} \\ \text{Internal diameter (mm)} &= \frac{\text{Age (years)}}{4} \\ &+ 4.5 \text{ (for children over six years of age).} \end{aligned}$$

(It should be noted that tubes are sized according to the internal diameter and that there may be some variation in the external diameter depending on the manufacturer and style of tube.) Below the age of two years, this guide is not reliable and the use of any formula must be modified by individual considerations. The length of the tracheal tube is similarly important, the distance between the vocal cords and the carina being age- and height-dependent. Endobronchial intubation is a common hazard and the effect of flexion or extension of the neck in some procedures must be considered. The following formulae have been suggested as a guide to tube length:

$$\begin{aligned} \text{Length} &= \text{Age (years)} / 2 \\ &+ 12 \text{ (cm) for orotracheal intubation} \\ \text{Length} &= \text{Age (years)} / 2 \\ &+ 15 \text{ (cm) for nasotracheal intubation.} \end{aligned}$$

As for tube diameter, these formulae are useful guides but correct tube position must be confirmed by careful auscultation, capnography and, if necessary, a chest x-ray.

In older children approaching puberty, cuffed endotracheal tubes are used, reflecting the anatomical development of the airway.

Despite concerns about the potential for mucosal damage, the use of cuffed tubes (with high volume, low pressure cuffs) is increasing in younger children and even newborns.³⁸ Provided that adjustments are made to size calculations and that the reduced margin of safety for endobronchial intubation³⁹ is appreciated, this has been shown to be safe and may afford advantages in terms of gas leak and environmental pollution and may reduce the need for repeat intubation if an incorrect tube size is selected.

Endotracheal tubes are available in a variety of materials, although the use of PVC and silicone rubber is now almost universal with the exception of tubes designed for laser procedures, discussed under Laser endoscopy. Similarly, a range of configurations has been developed (**Figure 41.3**). Preformed tubes, such as the 'south-facing' Ring, Adair, Eluyn (RAE) tube,⁴⁰ 'north-facing' nasal tubes or armoured tubes may be of particular benefit in head and neck procedures, allowing security of fixation with less interference in the surgical field than standard tubes.

A huge range of laryngoscopes and blades is available. Anatomical considerations and, to some extent personal choice, determine the most appropriate blade to use. In general, the relatively cephalad position of the infant larynx and the long epiglottis makes intubation easier with a straight-bladed instrument and these are often used in children under six months of age. Mackintosh pattern curved blades used in older children are positioned in the vallecula and indirectly lift the epiglottis. Vagal innervation of the posterior epiglottis makes bradycardia a potential hazard of the use of a straight-bladed technique. Various blade designs, with different cross sections and shapes, are produced, as well as different blade lengths. Not infrequently, failure to position and stabilize the head correctly can lead to intubation difficulties. Attention to basic details such as this should be assured before resorting to additional equipment.

Bougies or introducers over which a tube can be advanced are often helpful but care must be taken to avoid trauma to the larynx or trachea. In situations where anatomical abnormalities present particular problems, the use of a fiberoptic technique is often successful provided the operator is trained and practised in the use of such equipment.

Vascular access

Secure access to the circulation is mandatory for all children undergoing anaesthesia. Intravenous access should be obtained before induction of anaesthesia in emergencies, where fluid resuscitation is necessary or when an intravenous induction of anaesthesia is planned.

© Hodder Arnold / Scott-Brown 7E

Figure 41.3 Endotracheal tube patterns. From above; 'RAE' north and south facing, armoured uncuffed, cuffed and uncuffed pvc, Portex 'Ivory' for nasal intubation with metal 'Magill' connector.

The use of topical local anaesthetic creams (see under Premedication) is increasingly common in paediatric practice and has led to an increase in the use of intravenous induction of anaesthesia in children of all ages.

Intravenous cannulae are available in a range of designs and size, generally made from inert materials such as Teflon, polyurethane or silicone. Appropriate sites for cannulation depend on the age of the child.⁴¹ Following cannulation, secure fixation should be ensured and attention taken to ensure access to the cannula after positioning and draping for surgery.

In some situations, central venous or arterial cannulation may be necessary. Such interventions should not be undertaken lightly and performed only by those trained in the appropriate techniques.

Heat conservation

Control of body temperature is an important consideration in paediatric surgical patients. Most children become hypothermic to some degree unless active measures are taken to avoid this. Hypothermia results partly from environmental exposure but more importantly from anaesthesia-induced failure of thermoregulatory control.

Even a modest reduction in body temperature may be undesirable; consequently measurement of body temperature and active measures to conserve heat should be a standard part of paediatric anaesthetic practice.

General anaesthesia inhibits normal thermoregulatory mechanisms and superimposed heat loss to the environment predominantly radiant in nature increases the likelihood of hypothermia. Different body tissues have different temperatures and measurements are usually described as 'core' or 'peripheral'. Measurement of core temperature is of greatest clinical importance and thermocouple or thermistor thermometers are widely available. Common sites for core temperature measurement, such as the nasopharynx, distal oesophagus or tympanic membrane, may be inappropriate during ENT surgery!

Avoiding unnecessary exposure of the child is a simple, but effective, method of reducing heat loss, the area of skin covered being more important than the material used. In particular, the large surface area of the head in infants should remain covered if possible. Similarly raising the ambient temperature will help, although the temperature required to maintain normothermia in neonates (c. 26°C) can create uncomfortable working conditions in the operating theatre. Hence, maintenance of the room temperature at a comfortable level and

warming the microclimate around the child is more usual practice.

A number of warming devices are available, but forced warm-air convective blankets appear to be the most effective and are commonly used in paediatric practice.⁴² When active warming devices are used, temperature monitoring is mandatory to guard against unintentional hyperthermia.

Induction of anaesthesia

The transition from an awake to an anaesthetized state creates a number of physiological changes, with potentially hazardous consequences. It is the responsibility of the anaesthetist to conduct a safe induction of anaesthesia whilst maintaining a calm and unhurried manner that will reassure the child and, commonly, accompanying parents and carers. Immediately before induction of anaesthesia, patient identity, preparation and consent for all procedures should be confirmed. The function of any anaesthetic and ancillary equipment should be checked and the availability of appropriate drugs and, importantly, skilled assistance should be assured.

Parental presence during the induction of anaesthesia is now the norm in UK paediatric practice and is generally agreed by both anaesthetists and parents to be helpful. The anxiety felt by many parents should not be underestimated and it is important that accompanying their child is a choice rather than compulsory.

The changes that accompany induction of anaesthesia necessitate careful monitoring, both by clinical observation and through the use of physiological monitoring devices. It is often possible to apply monitoring equipment prior to the induction of anaesthesia and pulse oximetry is viewed as essential in this respect. ECG and blood pressure monitoring are desirable, but may be deferred until after induction in healthy children.

Inhalational induction of anaesthesia has been the mainstay in paediatric anaesthesia and remains in common use. The development of agents such as Sevoflurane, with low blood gas solubility (hence rapid induction), less cardiovascular depression than older agents and a less pungent odour has allowed smoother and more rapid anaesthesia.⁴³ The use of topical anaesthetic creams and the availability of fine gauge cannulae have similarly improved the acceptance of intravenous anaesthesia in children.

Frequently, the choice of induction technique is of no great clinical significance and is often influenced by personal preference, either on the part of the anaesthetist or the child. However, clinical considerations may influence the choice of technique, for example in the child with a difficult or partially obstructed airway most anaesthetists regard an inhalational technique as the safest, allowing the maintenance of spontaneous respiration.

Physiological monitoring during anaesthesia

Modern anaesthesia is expected to provide optimal conditions for surgical interventions whilst ensuring patient safety, minimizing morbidity and mortality. Advances in the last 20 years have allowed the development of equipment that provides almost instantaneous detection of physiological changes, particularly respiratory and cardiovascular, which has greatly enhanced the safety of paediatric anaesthesia. Minimum standards for monitoring during anaesthesia^{44, 45} have been widely adopted, although it must be appreciated that increasing reliance on complex electronic equipment, which may fail, should assist rather than replace basic clinical monitoring and that interpretation of information must be guided by the individual clinical situation.

Routine patient monitoring includes ECG, pulse oximetry, blood pressure measurement and capnography. The importance of temperature monitoring, particularly in infants, is mentioned under Heat conservation. Routine monitoring, particularly of respiratory function and oxygenation should be continued during recovery from anaesthesia. Unfortunately, monitoring the effect of anaesthetic agents on the brain is difficult and although methods based on processed EEG signals may be used,⁴⁶ these may be cumbersome and impractical in routine clinical practice. Monitoring of neuromuscular blockade is advisable, particularly in neonates or during prolonged procedures, primarily to ensure adequate recovery from relaxants at the end of surgery. During some procedures, for example parotid surgery, the surgical team may rely on stimulation of the facial nerve to avoid damage to this structure. In such surgery, monitoring of neuromuscular transmission is of particular relevance to ensure a muscular response to nerve stimulation. In some situations, patient or procedure considerations may merit more complex or invasive monitoring such as central venous pressure, direct arterial pressure, blood gas estimation or cardiac output measurement.

SPECIFIC SURGICAL PROCEDURES

The principles of preoperative preparation and conduct of anaesthesia described under Preoperative assessment outline the general approach to the paediatric surgical patient. Whilst these are applicable to all procedures, specific surgical operations may require the use of particular techniques to allow adequate surgical access and to ensure patient safety and comfort.

Operations on the ear

MYRINGOTOMY AND GROMMET INSERTION

Ventilation of the middle ear in children is a common procedure usually performed on a day case or outpatient

basis. The majority of patients are satisfactorily managed with a standard inhalation or intravenous induction of anaesthesia and airway maintenance with an LMA provides good operating conditions⁴⁷ and may have some advantages over a simple face mask technique.⁴⁸ Despite the potential for nitrous oxide to increase middle ear pressure, its use is widespread for grommet insertion and has not been associated with increased postoperative vomiting.⁴⁹ Paracetamol or nonsteroidal antiinflammatory agents afford adequate postoperative analgesia in most patients.^{50, 51} Modification of anaesthetic technique or overnight hospital admission may be necessary in grommet insertion cases in a significant minority of children with underlying conditions (such as palatal clefting, craniofacial or chromosomal anomalies) or with coexisting adenoidal hypertrophy and potential airway difficulties.

CONGENITAL EAR DEFECTS

Congenital defects of the ear may necessitate surgical intervention to reconstruct the external ear or for the implantation of bone-anchored hearing aids. Whilst the surgery is superficial and rarely of prolonged duration, the association of ear defects with other dysmorphic features of the face and mandible (particularly Treacher Collins and hemifacial microsomia syndromes) may pose significant anaesthetic concerns. These may include difficulties in visualizing the larynx and tracheal intubation^{52, 53} and careful assessment and planning of airway management are essential. Scrutiny of previous anaesthetic records can provide valuable information regarding airway management strategies. Fortunately, unless mouth opening is very severely limited, the LMA often allows adequate airway maintenance for these patients.⁵⁴ If tracheal intubation is necessary, a full range of equipment to assist in the management of difficult intubation and experienced assistance is essential.

MIDDLE EAR EXPLORATION, MASTOIDECTOMY, MYRINGOPLASTY, COCHLEAR IMPLANTATION

Anaesthesia for middle ear surgery requires an appreciation of the conditions necessary for successful microsurgery including a quiet, bloodless field, the influence that nitrous oxide may have on a tympanic graft and, in some procedures, the importance of preservation of the facial nerve.

Although adequate conditions may be achieved with a number of different anaesthetic techniques, common to them all is attention to detail. Careful preparation and judicious use of premedication will aid a smooth induction of anaesthesia avoiding hypertension and tachycardia. Subsequently, the avoidance of airway obstruction and minimizing mean airway pressure will help reduce venous bleeding which is often

more troublesome than arterial bleeding. When positioning the child for surgery, a 15 to 20° head-up tilt is helpful to reduce venous congestion, provided that compression of the neck, chest and abdomen is also avoided.

The rapidity with which depth of anaesthesia can be altered with modern inhalational or intravenous agents such as Desflurane and Remifentanyl means that hypotensive agents are rarely required.

Tracheal intubation and controlled ventilation is a common technique for middle ear surgery, although the use of a reinforced LMA may reduce the potential for airway complications at the end of surgery. Clearly, avoidance of coughing, laryngospasm and straining at the end of surgery is equally important as at induction of anaesthesia.

The solubility of nitrous oxide allows its diffusion into and out of air-filled spaces more rapidly than air leading to an increase in volume of the space, or an increase in pressure in noncompliant spaces such as the middle ear. Thus, pressure in the intact middle ear increases during nitrous oxide anaesthesia.⁵⁵ When nitrous oxide is discontinued, pressure falls as nitrous oxide diffuses out faster than air diffuses in. These pressure changes may distort or displace a tympanic graft and so nitrous oxide should be discontinued before the middle ear is closed.

The proximity of the facial nerve to the surgical field in some middle ear procedures demands careful monitoring to avoid nerve damage. A nerve stimulator may be used in the surgical field to identify branches of the facial nerve. It is important that the anaesthetist is aware of this and monitors the effect of any neuromuscular relaxant agents used.

The anaesthetic considerations for cochlear implantation are essentially the same as for other middle ear surgery although surgery, particularly if bilateral, may be prolonged. Profound sensorineural hearing loss may be associated with other features of relevance to the anaesthetist. For example, the prolongation of the QT interval in the Jervell and Lange-Nielsen syndrome presents a daunting challenge.⁵⁶

Operations on the nose, nasopharynx and pharynx

CHOANAL ATRESIA

Bilateral occlusion of the posterior nares may cause acute respiratory distress in the neonatal period and maintenance of a patent oral airway or, sometimes, endotracheal intubation is necessary until surgical intervention is undertaken. Repeated anaesthesia may be required for nasal dilatation and restenting during early infancy. In some cases, the cytotoxic agent Mitomycin C may be topically applied following nasal dilatation⁵⁷ and great

care should be taken to avoid exposure of surgical, anaesthetic and theatre staff.

ADENOIDECTOMY AND TONSILLECTOMY

Adenotonsillectomy remains one of the most common paediatric surgical procedures and comprises much of many anaesthetists' paediatric practice. Although often considered a routine procedure, a minority of patients with severe upper airway obstruction from adenotonsillar hypertrophy present stern challenges for even the most experienced anaesthetist. Considerable variation in pre-, intra- and postoperative management of children undergoing adenotonsillectomy exists and controversies abound.

Preoperative assessment is informed by the indication for adenotonsillectomy and, as indicated above, identification of children with OSAS is of great importance when planning intra and postoperative care. Although largely a clinical diagnosis, sleep studies with pulse oximetry and cardiological assessment may be required in children with severe or longstanding symptoms. Prediction of postoperative apnoea and hypoxia in children with severe OSAS will necessitate careful observation with pulse oximetry, supplemental oxygen and occasionally airway support.^{11,12} Particular difficulties may be expected in younger children under three years old¹³ and those with other congenital or acquired anomalies. Routine preoperative coagulation testing for healthy children is not generally indicated unless a history of bleeding tendency is suspected.⁵⁸

Factors dictating an appropriate anaesthetic technique include the preoperative and expected postoperative degree of airway compromise, airway security during surgery, postoperative pain relief and control of nausea and vomiting, postoperative bleeding and the proposed duration of hospital stay. In addition, recent concerns regarding the potential transmission of prion disease (variant Creutzfeldt Jakob disease) have, in the UK, determined anaesthetic technique to some extent.

In children with significant obstructive symptoms induction of anaesthesia may precipitate severe obstruction, which can usually be improved by continuous positive airway pressure (CPAP) and the insertion of an oropharyngeal airway. In such patients, a technique employing endotracheal intubation, ventilation and minimal opiate use affords good operative conditions and an awake child at the end of surgery. Careful postoperative observation with supplemental oxygen therapy and sometimes nasopharyngeal airway support or even tracheal intubation may be needed in the most severely obstructed patients. Particular attention should be directed to the care of such children on the first postoperative night.

Protection of the airway from blood and tissue debris is essential during surgery. To achieve this, most anaesthetists employ endotracheal intubation or the reinforced LMA. Tracheal intubation, usually with a

© Hodder Arnold / Scott-Brown 7E

Figure 41.4 Insufflation of oxygen and volatile anaesthetic agent via nasopharyngeal tube.

preformed plastic RAE pattern tube⁴⁰ (see **Figure 41.4**) has been the mainstay of airway management prior to the introduction of the reinforced LMA and is usually satisfactory for both surgeon and anaesthetist. Potential problems inherent in the fixed length of such tubes are well known and occasionally difficulties may be encountered with compression from the mouth gag, particularly if the gag is short or opened excessively. These difficulties are more likely with small tube sizes (less than 4.5 mm internal diameter) as is the potential for 'wedging' of the tube in the gag blade and accidental extubation of the patient when removing the gag.⁵⁹

The reinforced LMA has been widely used for tonsillectomy^{60,61} and may have some advantages over tracheal intubation. Placement of the mask does not require the use of muscle relaxants, creates a seal that protects the larynx from blood and debris and can be left in place to secure the airway until protective reflexes have returned. Use of the LMA requires full surgical cooperation and may necessitate particular care when positioning the mouth gag. Difficulties with surgical access⁶² may preclude the use of the LMA, particularly in smaller children (less than 15 kg) or when other complicating factors are present. A meta-analysis of the use of LMA in tonsillectomy concludes that this is a safe alternative to intubation provided full cooperation between surgeon and anaesthetist is ensured.⁶³

Analgesia following adenotonsillectomy in children has been achieved by a variety of means, most of which

Table 41.4 Suggested doses of paracetamol and NSAIDs in children.

	Loading dose (mg/kg)	Maintenance dose (mg/kg)	Dose interval (hours)	Maximum daily dose (mg/kg/24 h)
Oral paracetamol	20	15–20	4–6	90
Rectal paracetamol	30	20	6–8	90
Oral ibuprofen	5	4–10	6–8	20
Oral diclofenac	N/A	1	8–12	3
Rectal diclofenac	N/A	1	8–12	150 mg/day

involve a combination of paracetamol and nonsteroidal antiinflammatory drugs (NSAIDs), often with the addition of low-dose opioids such as codeine phosphate. The combination of paracetamol and codeine has long been used in paediatric practice and appears to be effective. Many anaesthetists use intravenous opioid drugs such as fentanyl or morphine intraoperatively, although this may increase postoperative nausea and vomiting and caution is advocated in the presence of severe obstructive symptoms. There has been much debate regarding the efficacy and safety of varying doses and routes of administration of both paracetamol and NSAIDs in children. A suggested dosage schedule is indicated (**Table 41.4**) based on the Royal College of Paediatrics and Child Health (RCPCH) guidelines.⁶⁴

Guidelines for the use of NSAIDs in the perioperative period based on a structured literature review have been issued by the Royal College of Anaesthetists.⁶⁵ There is good evidence for the analgesic efficacy of NSAIDs compared with opioids after adenotonsillectomy, although a risk of increased bleeding has been shown in some studies. The guidelines suggest that NSAIDs (but not paracetamol) be avoided in children with proven asthma, particularly if associated with nasal polyps, severe eczema or atopy, although most anaesthetists believe that it is reasonable to use NSAIDs in asthmatic children in whom previous exposure to these drugs has been uncomplicated. Studies published since this review are generally supportive of the analgesic benefits of NSAIDs although are not conclusive on the issue of increased bleeding risk.^{66, 67, 68} A recent systematic review concluded that the use of NSAIDs in paediatric tonsillectomy did not cause any increase in bleeding requiring a return to theatre and that there was less nausea and vomiting when NSAIDs were used compared to other analgesics.⁶⁹ It has been suggested that the surgical technique employed during tonsillectomy may influence postoperative pain although the evidence for this is conflicting.^{70, 71, 72} Similarly, the infiltration of the tonsillar bed with local anaesthetic agents is advocated by some authors,^{73, 74} whilst a systematic review of this practice concludes that there is no evidence that postoperative pain control is improved.⁷⁵

Nausea and vomiting following adenotonsillectomy is a significant problem in terms of patient comfort and

satisfaction and may delay discharge of children undergoing day care. The 5-hydroxytryptamine antagonists ondansetron and tropisetron are effective in reducing postoperative nausea and vomiting either alone or in combination with dexamethasone.^{76, 77}

Primary haemorrhage requiring surgical intervention in the first few hours following adenotonsillectomy is an uncommon (0.5–1 percent) but potentially life-threatening event that requires immediate attention. Blood loss is often difficult to estimate but clinical signs of tachycardia, pallor and reduced capillary refill should prompt intervention. Blood pressure is usually maintained in children until 25 percent or more of circulating volume has been lost and hypotension is a late and very worrying sign. Rapid volume replacement with crystalloid or colloid solutions should be instituted and hypovolaemia corrected whilst a theatre is prepared for surgery. During this time, blood is cross-matched and a full blood count and a coagulation screen performed.

The anaesthetic approach to a bleeding post-tonsillectomy patient must address the problems presented by the potential for regurgitation of swallowed blood together with active bleeding obscuring the view at laryngoscopy. Although opinions differ, most anaesthetists would favour a rapid sequence intravenous induction of anaesthesia with preoxygenation and cricoid pressure with the patient in a head down position on the operating table. In addition to the usual anaesthetic equipment, a back-up suction device and tracheal tubes smaller than that used at the original procedure should be to hand.

Following the provision of a secure airway, close cardiovascular monitoring and further fluid or blood transfusion are undertaken during surgery. The stomach should be emptied via a wide bore nasogastric tube and extubation should be performed with the child awake in a lateral, head down position. A postnasal pack placed to stem bleeding from the adenoid bed is poorly tolerated by younger children and may necessitate sedation and intubation in an intensive care unit until the pack is removed.

Adenotonsillectomy is now frequently performed on a day stay basis, particularly in North America, and appears safe provided that careful selection criteria and meticulous operative techniques are followed. Strict observation in the postoperative period, usually for four to six hours

postoperatively, is ensured and clear instructions issued for homecare and support following discharge. Despite an increase in day care tonsillectomy in the UK, many patients remain in hospital overnight, as much for social and organizational reasons as for clinical indications.

In recent years, the potential for transmission of vCJD via surgical equipment has prompted the UK Department of Health to implement improvements in decontamination procedures for surgical instruments, as advised by the Spongiform Encephalopathy Advisory Committee (SEAC).⁷⁸ In addition, adenotonsillectomy was identified as a procedure suitable to pilot the use of single use equipment as patients are generally young, a limited number of instruments are used and patient safety was unlikely to be compromised. Disposable surgical and anaesthetic equipment was introduced in 2001, but increased reports of adverse incidents prompted a withdrawal of the directive in December of that year. Although the return to reusable equipment was applied to anaesthetic and surgical equipment, it was subsequently decided, presumably on the basis of relative risk, that this change did not apply to anaesthetic equipment.⁷⁹ Currently then, anaesthetic equipment placed in the mouth or respiratory tract during tonsillectomy must be disposable or covered by a disposable protective sheath.

Airway endoscopy procedures

Anaesthesia for children undergoing airway endoscopy procedures requires an understanding of the medical condition and likely airway pathology, an appreciation of the surgical requirements for the procedure and the functions, hazards and limitations of bronchoscopic and laser equipment, close cooperation between all members of the theatre team and, not infrequently, a degree of ingenuity and adaptation.

DIAGNOSTIC AIRWAY ENDOSCOPY

Infants and children presenting for diagnostic laryngoscopy and bronchoscopy usually exhibit some degree of airway obstruction, stridor being the most frequent presenting feature. In many cases, a careful history of the onset and features of the obstruction will suggest a likely cause. Investigations, including chest and neck x-rays, barium swallow studies, respiratory function studies (although these are often difficult and unreliable in small infants) may further assist diagnosis.

Preoperative information is useful but preparation should be made for unexpected findings and a clear appreciation of the requirements of the surgeon and a cooperative approach are essential to allow accurate diagnosis to be made safely.

The anaesthetic technique must afford assessment of both fixed and dynamic elements of the airway whilst

ensuring airway maintenance and adequate oxygenation and ventilation of the child. An unobstructed view of laryngeal, tracheal and bronchial structures is necessary in a still, spontaneously breathing patient. Depth of anaesthesia must be sufficient to control the intense stimulation associated with laryngoscopy but also allow assessment of vocal cord and cricoarytenoid function without laryngospasm in the almost awake patient.

It is essential that a clear understanding exists between anaesthetist, surgeon and operating theatre personnel as to the conduct of the procedure. A range of airway equipment and experienced assistance should be available and all staff should be familiar with the assembly and use of bronchoscopic equipment. Sedative premedication is usually avoided in children with airway obstruction although may be useful in carefully selected patients (for instance frequent attenders) if anxiety is likely to worsen existing airway obstruction. Despite the general reduction in the use of anticholinergic premedication in children, most anaesthetists continue to use these agents in airway endoscopy procedures. The benefits include control of secretions, reducing the incidence of breath holding and laryngospasm, attenuation of vagal responses to airway instrumentation and deep inhalational anaesthesia, as well as more effective topical anaesthesia of the larynx.⁸⁰ Traditionally, atropine has been used preoperatively for this purpose, either orally or intramuscularly, and certainly is effective. The unpleasant sequelae of this practice for the child (i.m. injection, dry mouth, and diplopia) should be considered and many anaesthetists now employ intravenous atropine or glycopyrrolate at the time of induction of anaesthesia. The technique most commonly employed for diagnostic airway examination involves a volatile anaesthetic agent in combination with topical anaesthesia of the larynx. Maintenance of spontaneous ventilation, certainly until it is established that positive pressure ventilation is possible, is paramount and, in general, an inhalational induction is recommended using 100 percent oxygen and an increasing concentration of volatile agent. Historically, halothane has been the agent of choice but is increasingly being superseded by sevoflurane, which affords a more rapid induction. Debate continues over the place of halothane in paediatric anaesthesia,⁸¹ although its availability and cost mean that it is still widely used worldwide.

Airway obstruction prolongs the induction of anaesthesia and gentle assistance of ventilation with the application of CPAP may speed the process and improve gas exchange. Intravenous access, if not already secured, is obtained and depth of anaesthesia increased. Some anaesthetists choose to intubate the trachea following induction of anaesthesia, affording airway security for transfer to theatre and setting up of equipment. Intubation, however, may be difficult and muscle relaxants should not be used to facilitate this unless positive pressure ventilation is shown to be possible. Others avoid this to allow a surgical view of the unsullied

larynx. If intubation is performed at this point, the nasotracheal route is convenient, allowing the tube to be withdrawn into the nasopharynx for endoscopy.

Topical anaesthesia of the larynx, commonly using lignocaine, is an essential component of the anaesthetic technique to reduce coughing and laryngospasm and to allow assessment of vocal cord and cricoarytenoid function at very light planes of anaesthesia and during awakening. Although there are some concerns that topical anaesthesia may produce subtle changes in glottic function, and one study reports exaggeration of the magnitude of the signs of laryngomalacia in sedated children undergoing flexible bronchoscopy,⁸² the benefits outweigh these considerations.

The glottis, vallecula and trachea are anaesthetized, usually by the application of lignocaine spray. There is considerable risk of laryngospasm during spontaneous ventilation and often a short-acting muscle relaxant is used if intubation has not been performed. It appears, however, that the use of relatively dilute (2 percent lignocaine) solutions without preservative and flavourings found in multi-use metered dose sprays, significantly reduces the risk of laryngospasm (personal observation). Systemic effects from absorption of local anaesthetic agents from the mucosa may occur and it is recommended that dosage is limited to 4–5 mg/kg.

During the examination of the airway, spontaneous ventilation is maintained and anaesthesia is continued by insufflation of oxygen and a volatile agent, usually via a tracheal tube placed in the nasopharynx (**Figure 41.4**). This 'open' technique is well established, allows spontaneous ventilation to be maintained and has the merit of simplicity. Of major concern, however, is contamination of the working environment with volatile anaesthetic agents and occupational exposure of theatre personnel to concentrations considerably higher than currently recommended health regulation guidelines permit.⁸³ Alternative techniques for maintenance of anaesthesia, using intravenous agents such as propofol in place of volatile agents, are well described⁸⁴ and increasingly employed, even in small infants.

If intubation is not undertaken during anaesthetic induction this might form part of the examination to 'size' the larynx and subglottis allowing documentation of any stenotic lesions based on the external diameter of the endotracheal tube. This information is important when serial examinations are undertaken and also extremely useful anaesthetic information should the child present for other surgical procedures. At the end of the procedure the patient is allowed to waken with the laryngoscope in the vallecula to assess vocal cord function fully.

Careful monitoring of cardiovascular and respiratory function is imperative during endoscopy procedures and it is important that the operator, as well as the anaesthetist, are aware of any changes, particularly hypoxia or hypoventilation that may necessitate interruption of the examination or urgent intubation of the

trachea. In this respect pulse oximetry with an audible tone and a camera allowing the anaesthetist to view the surgical field are particularly helpful in promoting patient safety.

Following the examination, careful observation and continued monitoring is necessary as instrumentation may exacerbate the pre-existing airway problems. Although infrequently necessary, facilities for immediate tracheal intubation should be at hand. Humidified oxygen is often used during the recovery phase and nebulized adrenaline may be useful if airway oedema is suspected. If topical anaesthesia has been applied to the larynx, oral fluids should be withheld for one to two hours postoperatively. Many anaesthetists administer intravenous steroids such as dexamethasone to children undergoing these procedures in an attempt to reduce the development of oedema. Although evidence suggests that this may reduce post-extubation stridor in children and reintubation rates in neonates in intensive care units,⁸⁵ the value of steroids during airway endoscopy is questionable. Limiting the number and duration of airway instrumentations and ensuring that appropriate calibre endoscopes are used is probably of greater importance.

BRONCHOSCOPY

Anaesthetic considerations and techniques for rigid bronchoscopy are essentially the same as for diagnostic laryngoscopy. The use of Storz scopes with Hopkins telescopic rods is almost universal (**Figure 41.5**) affording excellent optical quality and ease of anaesthetic delivery via a side arm that allows connection to the anaesthetic breathing system.

Insertion of the telescope effectively closes the system allowing ventilation of the trachea, although there is a considerable resistance to airflow, particularly with small scopes, and assisted ventilation is often required in infants. Occasionally, it is necessary to withdraw the telescope temporarily to allow adequate oxygenation or ventilation.

Adequate topical anaesthesia of the lower airways is often difficult to achieve and coughing may be a problem when the scope is advanced to the carina and beyond,

Figure 41.5 'Storz' bronchoscopy equipment.

despite deep anaesthesia. Intermittent neuromuscular blockade may be used, provided adequate ventilation via the bronchoscope is assured, but this may preclude a full dynamic assessment of the lower airways. As in laryngoscopy, constant communication and cooperation between surgeon and anaesthetist is essential.

Fibreoptic bronchoscopes may also be used to evaluate the upper and lower airways,⁸⁶ increasingly so with the availability of ultra-thin scopes suitable for use in infants. Although the procedure may be performed under sedation, anaesthesia may be necessary. The use of an LMA through which the bronchoscope is passed allows safe airway management whilst affording easy passage and manoeuvring of the fibrescope.⁸⁷

FOREIGN BODY REMOVAL

Removal of an inhaled foreign body is a common indication for bronchoscopy in toddlers. Foreign body inhalation may precipitate acute airway obstruction and require urgent intervention or, more commonly, presentation may be delayed if a small object that passes beyond the main bronchi is inhaled. The conduct of anaesthesia is largely the same as for diagnostic endoscopy although the procedure may be prolonged and require multiple instrumentation of the airway. A spontaneous respiration technique, as described above, is frequently employed with volatile or intravenous anaesthetic agents. Some advocate controlled ventilation via the bronchoscope with neuromuscular blockade although caution should be exercised if a tracheal foreign body is likely to produce distal air trapping.⁸⁸ Whatever anaesthetic technique is employed, both anaesthetist and endoscopist should be aware of the potential difficulties involved. Airway inflammation and oedema, particularly when an organic foreign body is present, exacerbated by prolonged instrumentation and if removal is difficult, merits careful observation and follow up.

Operative procedures of the airway

Advances in microscope and laser technology have allowed the development of operative procedures on the paediatric airway that require particular attention from the anaesthetist. Frequently, patients with varying degrees of airway obstruction undergo repeated procedures and the special risks associated with the use of lasers must be taken into account.

Although the techniques described for diagnostic examination of the airway are satisfactory for many surgical procedures, alternative methods for airway management have been employed with varying degrees of success. The simplest of these involves intubation with a small tracheal tube that can be withdrawn into the nasopharynx when surgical access is impeded and

anaesthesia is continued with insufflation of oxygen and volatile agents as described above. Intermittent apnoeic oxygenation is a modification of this technique using neuromuscular blockade and intravenous maintenance of anaesthesia. Following a period of ventilation, the endotracheal tube is withdrawn to allow surgical access and reinserted repeatedly to allow intermittent ventilation, surgery being interrupted for this. Although successful and safe provided that close monitoring and a cooperative approach are ensured, infants tolerate only short periods of apnoea and repeated intubation may traumatize the airway.

Venturi jet ventilation involves entrainment of air produced by the delivery of high pressure gas boluses from a cannula attached to the suspension laryngoscope⁸⁹ or placed in the trachea. Muscle paralysis is maintained and ventilation monitored by observation of chest movement. Great care is taken to ensure that the cannula is correctly aligned and unobstructed at all times as gastric distension or direct injury to the airway from the high pressure jet may occur. This technique is not suitable when there is significant obstruction at glottic level as serious barotrauma may result. Trans-tracheal high frequency jet ventilation uses a similar principle where ventilation is provided by a high frequency jet ventilator via a cannula inserted percutaneously into the trachea via the cricothyroid membrane.⁹⁰ The driving pressure is similar or less than that used during conventional ventilation, reducing the risk of barotrauma, and the technique is suitable for use when there is significant obstruction at laryngeal level. Injuries such as extensive surgical emphysema may occur if the catheter is misplaced and a special jet ventilator is required. Use of these techniques will allow adequate anaesthetic and surgical conditions for the majority of procedures. In some children, however, the degree of airway obstruction may necessitate tracheostomy for treatment to be undertaken safely. The availability of tracheostomy equipment and the ability to secure the airway rapidly is mandatory when undertaking laryngeal surgery in children.

Laser endoscopy

Use of the carbon dioxide and other laser technology is well established for the treatment of laryngeal papillomatosis and other lesions of the larynx and trachea in children.⁹¹ The hazards of laser use (see Chapter 58, Laser principles in otolaryngology, head and neck surgery) must be appreciated by all theatre personnel and strict guidelines followed during laser activation.

Apart from general considerations, the major difficulty with laser surgery is safe airway management and the avoidance of airway fires caused by ignition of non-metallic materials. The choice of anaesthetic technique

Figure 41.6 Laser endotracheal tubes. 'Lasertrach' copper wound red rubber tube (above), 'Laserflex' uncuffed and double-cuffed tubes (below).

will depend on the lesion being treated, patient size and, to some extent, the preferences of surgeon and anaesthetist. Often a tubeless technique with insufflation of oxygen via a nasal catheter and maintenance of anaesthesia with volatile or intravenous agents is satisfactory, safe and reduces the risk of mishaps. This technique is widely employed and appears safe and efficient for children undergoing treatment of recurrent laryngeal papillomatosis.⁹² Although concerns have been raised about the use of high oxygen concentrations in the presence of laser energy, many children require this to avoid hypoxia and, provided all sources of combustion are avoided, the risk appears minimal.

If tracheal intubation is necessary, disposable metal or foil protected tubes are available in a range of sizes down to 3 mm internal diameter (**Figure 41.6**). All of these tubes, however, are either lined with PVC or have a rubber core and so there is a small risk of ignition. Cuffs on the larger tubes are also made from PVC or rubber and should be filled with saline rather than air. The construction of these tubes is such that the external diameter is large when compared to a standard tube of the same internal diameter and care should be taken to avoid trauma to the airway. In children with a tracheostomy, the tube should be removed or replaced with a metal tube before the laser is activated. Similarly, if trans-tracheal jet ventilation is used, the cannulae should be metallic.

Although every effort is made to reduce the risk of ignition, prompt action is required in the event of an airway fire to minimize the damage. Any combustible material should immediately be removed and oxygen delivery stopped. The fire should be extinguished with saline or water and ventilation resumed by mask. A thorough and careful examination of the airway is performed to assess damage and formulate a management plan that may include prolonged intubation or urgent tracheostomy.⁹³

ARYEPIGLOTTOPLASTY

Laryngomalacia is a common indication for laryngoscopy in infants and aryepiglottoplasty may be indicated. Following diagnostic endoscopy, anaesthesia can be continued with an insufflation technique or, commonly, a nasotracheal tube is inserted.⁹⁴ The child can be extubated at the end of surgery and although careful observation is necessary, postoperative problems are rare. Some surgeons prefer to use the carbon dioxide laser rather than microlaryngeal instruments for supraglottoplasty, in which case full laser precautions are necessary.

LARYNGEAL CYSTS

Laryngeal cysts are uncommon but may give rise to intermittent airway obstruction. Anaesthetic considerations are essentially the same as for any other cause of upper airway problem, although positive pressure ventilation may be impossible if the cyst produces a ball-valve obstruction to the larynx. Although intubation is usually possible, urgent aspiration of the cyst may be required if the larynx is completely obscured. Following definitive deroofing, extubation and recovery are usually uneventful.

LARYNGEAL CLEFTS

Posterior deficiency of interarytenoid tissue may prevent complete glottic closure and result in repeated episodes of aspiration and recurrent pulmonary problems. This may be attributed to other pathology frequently present in these infants. Minor clefts may be closed by direct suture using a microlaryngeal technique under orotracheal anaesthesia. Long clefts are associated with significant morbidity and mortality and usually require tracheostomy and gastrostomy for pulmonary protection.

Anaesthetic and surgical management of these patients is complex and repeated procedures may be necessary.

Laryngotracheal stenosis and reconstruction

ANTERIOR CRICOID SPLIT

Cricoid split procedures are usually undertaken in neonates (often premature) with mild stenosis of the cricoid ring. These infants frequently present as extubation failures following a period of neonatal intubation and ventilation. Endotracheal intubation and positive pressure ventilation are continued during the procedure and, following laryngofissure, a larger sized tube is placed to stent the larynx for five to ten days postoperatively. The tip of the tube must be positioned distal to the split and securely fixed. Postoperatively, meticulous intensive care management is required to ensure that reintubation, which may cause extensive damage, is avoided. Should extubation fail following a cricoid split, tracheostomy is usually necessary.

LARYNGOTRACHEAL RECONSTRUCTION

Reconstructive procedures on the larynx usually involve laryngofissure and interposition of an anterior and/or posterior cartilage graft to widen the lumen. The procedure may be single-stage, following which the larynx is stented with an endotracheal tube for a short period postoperatively or as a staged procedure if a tracheostomy has already been performed to secure the airway.

The anaesthetic technique for the single-stage procedure is as for cricoid split and postoperative management in an intensive care environment is essential to ensure tube patency and minimize laryngeal trauma. A similar technique is employed when treating suprastomal collapse in patients with a tracheostomy.

To allow surgical access the head is extended and the existing tracheostomy tube is replaced with a reinforced tube that can be sutured or taped to the chest during surgery. If possible, a cuffed tube is used to avoid tracheal soiling with blood and debris and also to prevent anaesthetic gas leakage via the opened airway. Dilation of the tracheostome may be necessary to allow insertion of an appropriate calibre endotracheal tube. In smaller patients the cuff may impinge into the surgical site or a risk of endobronchial intubation may necessitate the fashioning of a shortened preformed tube. In this case, leakage of anaesthetic gases may make adequate ventilation of the patient difficult at some stages of the procedure and close monitoring of gas exchange is vital. However the trachea is managed, constant vigilance is required to maintain airway patency and avert displacement of the tube during surgical manipulations.

If an anterior costal cartilage graft is taken, the possibility of a pneumothorax must be recognized. Significant pain may also result from the graft site and infiltration with local anaesthetic agents and postoperative opioid analgesia are often required. A chest x-ray is essential at the end of the procedure to exclude a pneumothorax. Postoperatively, airway secretions are increased and aspiration may occur if the stent causes glottic incompetence.

Tracheostomy

Many children undergoing tracheostomy are intubated and anaesthesia is continued via the existing tracheal tube. Initially, spontaneous ventilation and topical anaesthesia of the larynx may be advised if it is proposed to extubate the child for a brief examination of the airway before reintubation and tracheostome formation. In the unintubated child, inhalational induction of anaesthesia is usual, followed by intubation with an appropriate sized endotracheal tube. A range of tubes should be available if subglottic stenosis is present, the smallest Portex tube having an internal diameter of 2 mm. Occasionally, a pinhole subglottic airway will preclude intubation even with the smallest tube in which case an LMA or face mask with spontaneous ventilation may prove an adequate technique.

Before surgery an appropriate sterile breathing system and connectors should be selected and the ability to connect the tracheostomy tube to the breathing system is checked. Secure intravenous access and full cardiovascular and respiratory monitoring are essential during the procedure and attention should be paid to temperature maintenance, particularly in small babies. Surgical drapes should be placed in such a way that immediate access to the endotracheal tube is assured should airway difficulties occur during surgery.

The child is ventilated with 100 percent oxygen prior to tracheal incision and under direct vision the tip of the tracheal tube is withdrawn to allow insertion of the tracheostomy tube. The tube should not be removed from the larynx until correct placement of the tracheostomy is checked, to allow reinsertion should difficulty be experienced in tracheostomy insertion. Anaesthesia is continued via the tracheostomy using a sterile connector and breathing system passed out from the surgical field. Careful inspection of chest wall movement, chest auscultation, oxygen saturation and end tidal carbon dioxide measurement are imperative to assure correct placement of the tracheostomy tube.

At the end of surgery, the tracheostomy tube is secured with ties or tapes and careful suction of the pharynx and tracheostomy tube is performed. If tracheal 'stay' sutures have been placed in the tracheal wall, these should be carefully marked and instructions issued for the management of accidental tube dislodgement.

KEY POINTS

- ENT surgery provides the core of many anaesthetists' paediatric practice.
- Local organization of surgical services for children is in a state of flux.
- Careful preoperative assessment and preparation is vital for the safe conduct of anaesthesia.
- Relatively recent advances in technology and understanding of paediatric physiology have led to significant improvements in anaesthetic practice.
- Attention to detail, particularly regarding airway management, is essential.
- Close cooperation between anaesthetist and surgeon and a mutual understanding of the problems faced by each affords better care for patients.
- Objective evidence to support clinical practice in paediatric anaesthesia is limited.

Interface between critical care and ENT	533		

INTRODUCTION

The development of the intensive care unit (ICU) and intensive care medicine (ICM) has been driven by advances in medicine/surgery, the need to treat acute illness in an older, sicker population and increased public expectation. The origin of the ICU (which is the official term now used in the UK in preference to ITU – intensive therapy unit) is usually attributed to the large Danish polio epidemic in 1952, when there were insufficient ‘iron lungs’ available to provide respiratory support to the victims. Mortality was decreased significantly by the use of life support techniques previously only applied in the operating theatre. Techniques such as positive pressure ventilation required the constant attendance of medical and nursing staff and therefore these patients were brought together in a specific area of the hospital. Since then, increasingly complex medical problems have been successfully managed due to the increasing ability of the ICU to take over the role of a failing (or failed) organ system until recovery occurs.

DEFINITION OF ICU, HIGH DEPENDENCY UNIT AND CRITICAL CARE

As explained above, the ICU is a geographically defined area in the hospital which utilizes specialized personnel and equipment to provide care for the critically ill.

Indications for admission to ICU are:¹

- patient requiring (or likely to require) mechanical ventilation;
- patients requiring the support of two or more systems;
- patients with significant chronic impairment in one or more organ systems who require support for an acute reversible failure of another organ system.

Patients with no chance of survival due to irreversible disease should not normally be admitted to ICU. The admission of those whose survival would result in an ‘unacceptable quality of life’ may also be unwise. However, since such issues revolve around subjective judgement and opinions, it is recommended that such cases be considered by very senior and experienced staff before ICU admission is granted (or denied).

The high dependency unit (HDU) may be defined as an area for patients requiring more intensive observation, treatment and/or nursing care than can normally be provided on a general ward.² Such units would not normally accept patients requiring mechanical ventilation for more than a few hours. Costs and staffing of such units are significantly less than that of ICU since the usual nurse:patient ratio is 1:2 or 1:3. It has a role as a ‘step-down’ unit providing an appropriate level of care for ICU patients who have reached a level of function which makes further ICU management unnecessary, but who are still too ill/unstable for care in a general ward. The HDU may also provide a ‘step up’ facility for patients who are

too unstable to be safely treated at general ward level. An HDU should ideally be adjacent to (or in a designated area within) an ICU and have strong clinical and managerial links with the ICU. Some ICUs have a mixed caseload of both ICU- and HDU-type patients and would not be viable if delivering only ICU support. Thus the management of illness in ICU and HDU can be seen as a continuum and the term 'critical care' is now used to cover this.³

STAFFING, STRUCTURE AND ROLE OF ICU AND HDU

It is no longer appropriate to view the ICU solely as a place where patients receive mechanical ventilation. The ICU should possess the means to support all the major organ systems including circulatory support, haemodialysis and other forms of renal support, nutritional support and the ability to treat coagulation disorders, severe infection and metabolic derangement.

ICU should gather in one area equipment, technical expertise and a high concentration of appropriately trained nursing staff which cannot be duplicated elsewhere in the hospital. Although ICU is always one of the most expensive areas for patient treatment (£1200–2500 STG/day), every hospital expected to treat severe acute illness requires this capability. Concentrating resources in one area is the most cost effective way to do this.

Patient management in ICU requires a team approach. Medical and nursing staff are the basis of this team but it also includes technical, physiotherapy and dietetic staff in addition to the input of radiology, bacteriology and other laboratory-based personnel. To weld this group together requires a medical director who has specific training and an ongoing interest in critical care and who spends the bulk (if not all) of his/her clinical time there.⁴ The other senior medical and nursing staff should also be specifically trained and be focused on critical care.

Medical responsibility for the patients in ICU varies from unit to unit and between medical systems. At one extreme, treatment is dictated by the referring service at all times. This is usually inappropriate since the people making decisions concerning treatment do not see the patient continuously and may not see 'all the pieces in the jigsaw'. Conversely, in some units all clinical decisions are taken by the ICU medical staff without any reference to the referring service. This may work and is a common model in Australia. At worst, however, it may lead to professional friction, poor staff relations and poor care. Many well-run units steer a middle path in which the decisions are made by the ICU team after discussion with the other relevant clinicians/support services.

An ICU should be large enough to ensure that it is never empty since this would result in the staff being deployed elsewhere and the unit being unable to respond

quickly to clinical needs. Therefore, a *minimum* of six bed spaces has been recommended. The average size of ICUs in many countries has been increasing as demand increases and units of 20+ beds are now commonplace. ICU requires a high nurse:patient ratio – 1:1 is viewed as appropriate within the UK.⁴ To achieve this, each bed requires approximately 6.5–7.0 nurses to cover shifts, weekends, holidays, sick and study leave. In addition, each unit needs 24-hour resident medical cover, i.e. a doctor who has no other clinical commitments, present physically in the unit at all times. Likewise, there must be 24 hour technical back-up available rapidly. Most units also have their own 'in house' laboratory which provides blood gas analysis (at least) and measurement of blood/plasma electrolytes, glucose, lactate, osmolality and some drug levels.

ORGAN SYSTEM SUPPORT

A substantial part of the benefit of ICU admission is due to attention to detail with immediate intervention and correction of deranged physiology. In ICU or HDU, patients have continuous monitoring of vital signs, frequent blood gas analyses, frequent checks on haematology and biochemistry, hourly calculations of fluid balance and trained staff immediately to hand 24 hours a day. This ability to have real time information about a patient's condition and to make appropriate changes in management/support is the hallmark of good critical care. Clinical management often involves initiation of or adjustment to organ support. We will now briefly consider some of the commonest forms of organ support in critical care.

Respiratory support

At its simplest, this may involve the use of high concentrations of well-humidified (warm) oxygen delivered via standard or continuous positive airway pressure (CPAP) mask in conjunction with aggressive regular physiotherapy. However, in ICU rather than HDU, it is likely to involve tracheal intubation and mechanical (positive pressure) ventilation.

In health, the work of breathing (WOB) accounts for only 2–3 percent of total oxygen consumption. With respiratory disease, required minute volume may quadruple, lung compliance is decreased and the efficiency of chest wall movements is reduced. The result is that WOB may require more than 20 percent of total oxygen consumption and precipitate tissue hypoxia and cardiac failure. WOB cannot be easily quantified but is associated with the clinical findings of increased respiratory rate, sweating, tachycardia and the use of accessory muscles of respiration. Following assessment, a patient with

respiratory difficulties may receive one or more of the following.

- Increased concentration of inspired oxygen by means of a well applied face mask, with a reservoir bag, high oxygen flow (12–15 L/min) and initiation of pulse oximetry. A patient with oxygen saturations below 90 percent, particularly with appreciably increased work of breathing, may require transfer to ICU or HDU.
- CPAP, applied via a tightly fitting face mask or hood and a suitable circuit with oxygen enriched air.
- Tracheal intubation, with maintenance of spontaneous respiration, usually via the oral route (with or without CPAP). Indications for tracheal intubation are as follows:
 - protection of the airway;
 - long-term correction/prevention of airway obstruction;
 - to facilitate positive pressure ventilation;
 - to facilitate broncho-pulmonary toilet.
 - This approach is useful when airway patency is in question or when removal of bronchial secretions is difficult. However, tracheal intubation alone may be of minimal clinical benefit in many cases since it does not address the problem of increased WOB.
- Mechanical ventilation (MV). The general indications for institution of mechanical ventilation are:
 - depressed respiratory drive;
 - inefficient respiratory effort/increased work of breathing;
 - abnormal pulmonary physiology.
 - More specifically the need for mechanical ventilation is often associated with one or more of the following findings:
 - $\text{PaO}_2 < 6 \text{ kPa}$ on 60 percent inspired oxygen;
 - $\text{PaCO}_2 > 8 \text{ kPa}$ with $\text{pH} < 7.2$;
 - evolving respiratory fatigue;
 - cardiovascular decompensation;
 - recent major/prolonged surgery;
 - multiple organ dysfunction.

Much of the benefit of MV is that it can completely abolish WOB since the patient may not have to initiate any spontaneous breaths. Unlike spontaneous respiration, MV requires the generation of positive intrathoracic pressure which may produce ventilator-induced lung injury (VILI) due to the effects of pressure (barotrauma) or lung stretch (volutrauma).⁵ Positive intrathoracic pressure may also reduce venous return to the heart and thus precipitate hypotension – particularly in the hypovolaemic patient. Modern ICU ventilators, with many different modes of ventilation,⁶ strive to reduce the complications of positive pressure ventilation, but there is no scientific evidence that any specific mode of ventilation is superior.

WEANING FROM MECHANICAL VENTILATION

This is a programme of gradual reduction in respiratory support which is specifically intended to (eventually) result in the patient breathing spontaneously (without any outside support) 24 hours/day. It suggests that the original cause of acute respiratory failure has been controlled or eradicated. Weaning may be achieved over a matter of hours, days or (occasionally) weeks. It is usually achieved by gradually reducing the support supplied by the mode of ventilation being used. There is no convincing evidence for one mode of ventilation being superior to others as a method of weaning, although pressure support weaning has gained converts in recent years. ICU patients who have had short periods of ventilation (24–48 hours) may wean perfectly well by being taken off ventilation abruptly to breathe spontaneously on a CPAP circuit (T-piece weaning).⁷

Cardiovascular support

The primary function of the circulation is to transport oxygen, nutrients, carbon dioxide and other waste products to and from cells. This requires adequate amounts of haemoglobin and oxygen and appropriate cardiac output/perfusion. The latter depends on circulating volume (preload), cardiac contractility and the vascular tone in the arterial/arteriolar system (afterload).

Normally, arterial blood (100 percent saturated with oxygen) contains approximately 20 mL O_2 /100 mL. With a normal adult cardiac output of 5000 mL/min, this gives a total oxygen delivery to the tissues of 1000 mL O_2 /min. Resting healthy adults use approximately 250 mL O_2 /min, i.e. the extraction ratio is only 25 percent and venous blood is (on average) 75 percent saturated with O_2 (15 mL/100 mL blood). There is, therefore, a large safety margin regarding the balance between O_2 supply and O_2 demand in health. This safety margin is felt to be eroded or absent in critical illness due to increased metabolic rate and decreased efficiency at the cellular level in utilizing available O_2 . Shock can be defined as inadequate perfusion (or O_2 delivery) for the needs of the tissue resulting in cellular hypoxia. Shoemaker *et al.*⁸ suggested that, since O_2 delivery does not keep up with increased tissue demand in critically ill patients, augmentation of O_2 supply by increasing cardiac output would lead to greater, beneficial tissue O_2 consumption. Although his specific targets (cardiac index $> 4.5 \text{ L/m}^2/\text{min}$, O_2 delivery $> 600 \text{ mL/m}^2/\text{min}$ and O_2 consumption $> 170 \text{ mL/m}^2/\text{min}$) have declined in popularity,⁹ the principle of maintaining good tissue oxygenation is the foundation of cardiovascular support. For this reason, the end-points of cardiovascular resuscitation are not based on heart rate and blood pressure, but on flow related clinical parameters such as capillary refill, urinary output, serial measurement of arterial lactate or plasma bicarbonate and objective measures of cardiac index (cardiac output/body surface area).

MONITORING OF CARDIAC INDEX AND PERFUSION

Perfusion can be assessed clinically using the clinical parameters above.¹⁰ In many situations, such serial assessments are all that is required. In a minority of cases, the severity of illness or the number of organ dysfunctions mean that more objective measures of cardiac function blood flow and perfusion are required.

The cardiac index (CI) may be measured noninvasively using ultrasound probes, either placed in the oesophagus behind the left atrium or in the suprasternal notch. A pulsed Doppler shift technique allows the measurement of flow velocity and (since the cross-sectional area of the aorta is also measured) the flow/unit time. Difficulties may arise in maintaining a good probe position. Transthoracic impedance plethysmography assesses CI by measuring the change in voltage across the chest in response to a high frequency current (usually 100 kHz). Changes in transthoracic resistance are assumed to be due to changes in blood volume which reflects cardiac filling and emptying. Unfortunately, the correlation between results obtained using the above techniques and the gold standard (invasive) technique is variable.

Invasive measurement of CI requires the placement of a catheter in the pulmonary artery. The principle use to measure CI is the reverse Fick principle. Short bursts of an electrical microcurrent is used to cause a heating effect in the plasma. Quantifying the resultant change in blood temperature allows continuous measurement of CI. It is important to balance the risks of insertion of insertion of a pulmonary artery catheter (PAC) with the benefit obtained. Changes in management prompted by information obtained from PACs has been shown to result in improved outcome in shocked patients who were not responding to standard therapy.¹¹ In contrast, failure to use PACs (and the information they provide) appropriately has been shown to be associated with poorer outcomes¹² and the risk of infection increases with time *in situ*.¹³ When it is no longer providing information which is being used to make clinical decisions, a PAC should be removed. The use of PAC has decreased in recent years and this trend is unlikely to change. The largest clinical study on the use of the PAC found no evidence of benefit or harm associated with its use.¹⁴ Increasingly, clinicians are using less invasive methods of measuring cardiac index at the bedside, e.g. (1) oesophageal Doppler and (2) lithium indicator dilution and pulse power analysis.

FLUID THERAPY – WHAT TYPE OF FLUID SHOULD WE USE?

All forms of shock, except cardiogenic shock, involve either true or relative hypovolaemia. Thus, expanding the blood volume by administration of fluids is the first step in cardiovascular resuscitation. The controversy regarding crystalloid or colloid fluid resuscitation has raged in the literature for decades.^{15, 16, 17} Fortunately, most clinicians

are not so extreme in their views and use a mixture of crystalloid and colloid fluids. Some points seem beyond argument:

- colloids are more expensive than crystalloids;
- colloids may cause anaphylactoid reactions (rarely);
- the use of either solution in initial resuscitation allows blood to be used more effectively and safely later in the patient's care;
- colloids are more time-efficient at restoring intravascular volume;
- plasma oncotic pressure is better maintained with colloid – this may or may not clinically advantageous.

The most important point in resuscitation is to ensure that the patient has received adequate fluid. This will often mean transfusing three to four times the volume of blood lost when using crystalloid replacement or one and a half to two times the volume lost using colloid. When appropriate, filling pressures and/or cardiac index should be measured using a central venous line or PAC. Many studies have suggested that resuscitation to supranormal levels of CI and tissue oxygen delivery may improve survival.^{8, 18} Even if global perfusion appears satisfactory, regional hypoperfusion may exist, particularly in the splanchnic bed.^{19, 20}

The best clinical guide to good organ perfusion is a urinary output of at least 1 mL/kg/hour without the influence of diuretics or hyperglycaemia. Oliguria is an important clinical sign of hypovolaemia and should frequently lead to a fluid challenge and not administration of a loop diuretic. The sequelae of persistent hypovolaemia are tissue hypoxia, multiple organ dysfunction and death. The sequelae of fluid overload (congestive cardiac failure, pulmonary oedema) may carry a lower associated mortality.

INOTROPES

Inotropes are agents which increase the force of myocardial contraction by a direct effect on the myocardium. Those used clinically are administered intravenously by continuous (accurately controlled) infusion and most are catecholamines or their synthetic analogues. The use of dopamine, for many years the most widely used inotrope, has declined due to doubts about its supposed dose-dependent effects,^{21, 22} and concerns about endocrine and immunosuppressant side effects.²³

The choice of inotrope is often determined not by its inotropic effects but by its other effects – either desirable or undesirable.²⁴ Often a major consideration is whether the drug is being given to improve arterial pressure or improve tissue perfusion. Dobutamine is an inotrope and vasodilator and is the preferred inotrope in many instances. It is a drug which improves perfusion although it has minimal and unpredictable effects on arterial pressure. It is often used in association with noradrenaline.

Adrenaline may improve perfusion and/or pressure and is sometimes used as a single agent in the treatment of septic shock. However, its unpredictable mix of alpha and beta adrenergic receptor stimulation and its potential to produce cardiac arrhythmias is a drawback. Noradrenaline also stimulates both alpha and beta adrenergic receptors but is particularly potent at alpha-receptors, thus it is an inotrope with vasoconstrictor effects. It will raise blood pressure and is often used to treat the hypotension associated with the generalized vasodilatation of severe sepsis/septic shock. It is often used in association with dobutamine in sepsis as dobutamine augments cardiac contractility in the face of sepsis-induced depression and the increased afterload due to noradrenaline.

The importance of the splanchnic circulation has raised interest in dopexamine. This dopamine analogue predominantly stimulates dopamine and beta-adrenergic receptors. It is a (weak) inotrope, vasodilator and (possibly) increases splanchnic blood flow. Studies have claimed that dopexamine beneficially improves oxygen flux in the postoperative period²⁵ and that it promotes better colonic mucosal perfusion,²⁶ though this has been questioned by other work.²⁷ A multicentre trial failed to show any outcome benefit from the use of dopexamine.²⁸

The manipulation of the cardiovascular system should follow a logical sequence. In general this sequence is

1. Is the cardiac output adequate? An inadequate cardiac output is suggested by hypotension, oliguria, cold peripheries, an elevated plasma lactate.
2. Is the low cardiac output due to hypovolaemia or poor myocardial function? Central venous pressure (CVP) measurement may be useful. A very low value (0–4 mmHg) suggests hypovolaemia and the CVP trend will guide fluid replacement. A high CVP (> 15 mmHg) suggests a cardiogenic (pump) problem which may improve with dobutamine (5–20 µg/kg/min).
3. The use of a PAC will give much greater information and should be considered whenever intelligent manipulations based on CVP measurements has failed to produce improvement.
4. Patients with sepsis have rapidly changing haemodynamic profiles. Invasive monitoring with appropriate pharmacological support should be initiated early in patients with septicaemia/septic shock.

Renal support

There are many factors associated with the development of acute renal failure (ARF) in the critically ill patient. These often coexist and are summarized in **Table 42.1**. Common pharmacological causes of ARF are high doses

of some radiological contrast media, toxic plasma levels of some antibiotics, e.g. the aminoglycosides, the use of nonsteroidal antiinflammatory agents, cyclosporin A and antimetabolites, e.g. cis-platinum and methotrexate.²⁹ As the understanding of the pathophysiology has advanced, strategies have been developed which might reduce the incidence of ARF. Adequate fluid replacement guided by central venous or pulmonary artery pressure, adequate blood transfusion, attention to oxygen transport and early nutritional support may all be important. The use of dopexamine (0.5–1.0 µg/kg/min) may increase renal blood flow and promote urine flow. Although such a strategy is often used in at-risk patients, there is no objective evidence that it prevents ARF. Previously, dopamine (2–3 µg/kg/min) was thought to have the same effect but the evidence for its potential benefit is now viewed as less convincing. Many clinicians now use n-acetyl cysteine as a pretreatment which may mitigate the renotoxic effects of radiological contrast.

Indications for renal replacement therapy (dialysis) can be summarized as the presence of hyperkalaemia, fluid overload, metabolic acidosis and a high plasma level of urea and creatinine. The absolute values of the latter which trigger the decision to dialyse varies between centres.

Until recent years, haemodialysis (HD) was usually performed for a three or four hour session on a daily or alternate day basis. Originally performed through surgical or plastic arteriovenous connections, short-term HD is now usually achieved using a double lumen catheter inserted in a large vein, e.g. subclavian or femoral. ICUs are increasingly performing continuous HD (often termed CRRT – continuous renal replacement therapy) over a 24 hour period.^{30, 31} This produces less cardiovascular instability as fluid and electrolyte shifts occur more gradually. The disadvantages are increased costs, need for continuous heparinization and the need for ICU staff training. No satisfactory comparison of these techniques has been performed, although there is evidence that CRRT produces normalization of plasma electrolytes, etc., more quickly than HD.³² Although there is some suggestion of better outcome with CRRT,³¹ this has been refuted by other studies.³³

Nutritional support

Simple starvation leads to the exhaustion of glycogen stores within 48 hours and an increase in glucose production from amino acids derived from breakdown of body proteins (gluconeogenesis). The glucose provided is used to fuel the brain and red blood cells which cannot normally utilize other substrate. This produces a rate of body protein breakdown which would be life-threatening if unchecked. Fortunately, in persistent uncomplicated starvation, the body switches to fat as the predominant energy source and the brain adapts to

Table 42.1 Causes of acute renal dysfunction.

Renal dysfunction	Cause
<i>Pre-renal dysfunction</i>	
Decrease in blood volume	Haemorrhage Dehydration Burns GI losses (vomiting/diarrhoea) Renal losses (diuretics, diabetes insipidus, adrenal insufficiency)
Decrease in effective blood volume (Renal hypoperfusion)	Cardiogenic shock Liver disease with ascites Hypoalbuminaemia Pancreatitis Peritonitis Hypercalcaemia Catecholamines Cyclosporine Amphotericin B Cyclooxygenase inhibition Angiotensin-converting enzyme inhibitors Renal artery stenosis/occlusion Hyperviscosity syndromes
<i>Intrinsic renal dysfunction</i>	
	Glomerulonephritis Vasculitis Acute tubular necrosis (ischaemia, drugs/toxins, pigments) Interstitial nephritis (antibiotics, NSAIDs, ACE inhibitors) Pyelonephritis Infiltration (sarcoidosis, lymphoma, leukaemia) Radiation nephritis
<i>Post renal dysfunction</i>	
	Papillary necrosis Ureteric obstruction (stone, tumour, retroperitoneal fibrosis) Bladder obstruction (tumour, prostatic enlargement, neurogenic dysfunction) Urethral stricture Posterior urethral valves Phimosis

use ketones as a metabolic fuel, thus allowing gluconeogenesis to slow.³⁴ Unfortunately, in critical illness (particularly when complicated by sepsis), gluconeogenesis is not suppressed and this has to be fuelled by rapid protein breakdown – the so-called hypermetabolic or hypercatabolic state in which the body is subject to a process which has been termed ‘autocannibalism’. Such protein breakdown has significant deleterious effects on organ function and outcome. By providing exogenous glucose, amino acids and other nutrients, we hope to modify this process.

Enteral nutrition (EN) is nutritionally, immunologically and metabolically superior to feeding using the total parenteral nutrition (TPN) route. The present preference for EN could be justified on the basis that it is less expensive, does not require central venous cannulation with its attendant complications and is less likely to

produce fluid overload, hyperglycaemia or hypophosphataemia. To fully appreciate the superiority of EN, we should consider the effects of critical illness and lack of luminal nutrients on the gastrointestinal tract.

The mucosal cells of the gastrointestinal (GI) tract have one of the highest turnover rates of any body tissue. An intact gut mucosa requires a balance between cell renewal and exfoliation. Its prime function is to allow the controlled absorption of nutrients while providing a barrier to the passage of toxins and bacteria from the lumen of the gut into the portal circulation. Barrier function is due to a series of elements: the intact mucosal layer, tight junctions between cells, lymphocytes, macrophages and neutrophils in the submucosa and Peyer’s patches and gut-generated IgA. The absence of nutrients within the gut lumen appear to compromise both gut mucosal health and barrier function.

Moore and colleagues³⁵ published a meta-analysis of eight studies comparing EN and TPN in surgical patients. Infective complications were significantly less in EN groups, with lower incidences of pneumonia, intra-abdominal abscesses and (not unexpectedly) catheter sepsis. It should be stressed that, even when catheter-related sepsis is excluded, TPN is associated with a significantly higher incidence of infective complications than EN. In animals, EN is associated with less intestinal mucosal atrophy, liver dysfunction, bacterial translocation, greater immunocompetence and better survival after a variety of systemic insults.

TIMING AND METHOD OF DELIVERING EN

Which clinical findings tell us when we might introduce enteral feeding? The presence of bowel sounds, though comforting, is irrelevant. Many patients with no bowel sounds may tolerate and absorb nasogastric feeds. In contrast, gastric stasis, leading to high aspirates and vomiting, may occur even when bowel sounds are present. Often, a low nasogastric aspirate (<250–300 mL in 24 hours) is the most appropriate prompt to initiate feeding. The common problem of gastric stasis may require the increasing use of feeding (surgical) jejunostomy tubes and the selective use of nasoduodenal or nasojejunal tubes. Persuading feeding tubes to negotiate the pyloric canal and remain in position can be a problem. Endoscopic guidance or fluoroscopy are useful – the latter having a 95 percent success rate – but may be logistically difficult in critically ill patients. With such strategies it is possible to feed patients via the enteral route within 24 hours of major surgery. Graham and colleagues,³⁶ in a controlled trial, showed that aggressive early jejunal feeding was associated with fewer infective complications and a shorter ICU and hospital stay than standard nasogastric feeding in head injured patients.

EN is usually administered by continuous infusion into the GI tract. This reduces GI side effects but may lead to increased Gram-negative colonization of the upper GI tract. Stopping enteral infusion for four hours to permit a (bactericidal) decrease in intragastric pH has been suggested as a strategy to reduce the incidence of Gram-negative pulmonary infection.³⁷ However, an extensive systematic review, while confirming the superiority of early EN over TPN, could not make recommendations regarding composition of feed, bolus versus infusion feeding and many other issues.³⁸ When patients have suffered a prolonged period of poor nutrition, initiation of feeding may produce severe hypophosphataemia and other electrolytic disturbances which may lead to acute respiratory failure, cardiac dysfunction and neurological problems – the so-called refeeding syndrome.³⁹ The daily maintenance requirements vary between patients and at different stages of their illness. Typical daily values for ICU patients are shown in **Table 42.2**.

Table 42.2 Typical daily fluid, electrolyte and nutritional requirements in critical illness.

Variable	Requirement
Water	35–40 mL/kg
Sodium	1–1.5 mmol/kg
Potassium	0.6–0.8 mmol/kg
Calories	20–30 kcal/kg
Nitrogen	0.2–0.3 g/kg (increased in severe illness)
Calorie:nitrogen ratio	150:1 (moderate illness) 100:1 (sepsis/MODS/hypercatabolism)

IMMUNONUTRITION

Immunonutrition seeks to use nutrients to modify the immunological response to illness and injury. Potential immunonutrients given by the enteral route include glutamine, arginine, omega-3 fatty acids and nucleotides. Glutamine and omega-3 fatty acids have also been administered parenterally. Their potential role is the preservation of cellular immune function and to beneficially alter the production of inflammatory mediators.

Glutamine is required both as a primary fuel and in the synthesis of nucleotide precursors by the immune system. It appears to be conditionally essential in the critically ill. Despite a large reserve, excessive demand for glutamine in such patients may cause glutamine deficiency, resulting in decreased intestinal integrity and cellular immune function.⁴⁰ Administration of parenteral glutamine has been associated with improved outcome in intensive care patients and patients having major elective abdominal surgery.^{41, 42}

In a small study, the use of enteral glutamine in burns patients was found to reduce the incidence of positive blood cultures and mortality but, puzzlingly, had no effect on length of care or polymorph phagocytosis.⁴³ A well-designed large study of enteral glutamine in ICU patients failed to show any benefit in terms of incidence of severe sepsis, death or a number of other secondary outcomes.⁴⁴ The Canadian Critical Care Group systematic review recommended glutamine in critically ill burns and trauma patients, but did not recommend the addition of arginine to EN.³⁸

An enteral feed rich in omega-3 fatty acids has been shown to decrease the requirement for supplemental oxygen, the period of ventilatory support, ICU length of stay and new organ failure in patients with moderate or severe acute respiratory distress syndrome.⁴⁵ The same group has more recently studied the mechanism of the improvement in pulmonary function and found a decrease in indices of alveolar membrane protein permeability and reduced levels of IL-8, leukotiene B4 and neutrophils in broncho-alveolar lavage fluid in patients fed on an enteral feed containing omega-3 fatty acids and enhanced antioxidants.⁴⁶ Parenteral omega-3 fatty acids show immune benefits and antiinflammatory

effects but no effect on infection rate or mortality in surgical patients.⁴⁷

Galban *et al.*⁴⁸ showed a reduction in mortality in critically ill patients with sepsis receiving immunonutrition, but benefit was confined to those with relatively low illness severity. Another study showed significantly increased mortality in critically ill patients receiving immunonutrition, an effect that was more pronounced in patients with sepsis.⁴⁹

The most recent meta-analysis found that the use of immunonutrition reduced infections and hospital stay, particularly in surgical (rather than critically ill) patients.⁵⁰ Despite these apparent benefits of immunonutrition, none (of three) meta-analyses have identified a significant effect on mortality, either globally or across any patient grouping.^{50, 51, 52}

INTERFACE BETWEEN CRITICAL CARE AND ENT

Postoperative care after surgery

Like other surgical specialties, ENT may refer patients for critical care management following (and occasionally prior to) elective or emergency surgery. This may be due to:

- the nature of the acute illness (e.g. major haemorrhage with shock after tonsillectomy or acute mastoiditis/sinusitis with signs of intracranial infection);
- the nature of the surgery (e.g. major head and neck surgery after which airway swelling and respiratory compromise might be expected in the postoperative period);
- patient factors (e.g. severe cardiac or respiratory disease in a patient requiring prolonged and/or extensive surgery).

Often, several of these factors coexist. In such cases the critical care phase may last just one to two days, or may be much longer – particularly in patients with severe cardio-respiratory disease in whom weaning from mechanical ventilation may be difficult. The development of severe infection or systemic inflammatory response syndrome (SIRS) is relatively frequent during critical illness and may lead to the development of multiple organ dysfunction syndrome (MODS) and, potentially, an increased length of stay (LOS) in ICU, morbidity and mortality. Good communication between the ICU staff, ENT staff and the relatives is important, particularly if this phase of care is prolonged and/or complications occur.

Post-head/neck trauma

The management of injuries to the head, face or neck may require ENT surgical intervention, either in the acute phase or after many days in ICU/HDU. Early intervention

may be required after major vascular or airway injury. Treatment of nasal injury or the drainage of blood-filled sinuses may be required later in the management of such patients. The assessment of actual or possible injury to the tympanic membrane or other parts of the auditory mechanism may also be required.

Management of the difficult airway

There are two common clinical scenarios. First, acute management of partial or complete airway obstruction. This is often in cases where it is suspected that tracheal intubation will be difficult or impossible. Airway obstruction may occur at any level:

- supralaryngeal – tumour, infection, anaphylaxis;
- laryngeal – infections, tumours, surgery, anaphylaxis;
- infralaryngeal – tumour, infection, tracheomalacia, subglottic stenosis.

The techniques required will vary. In many cases, the role of the ENT surgeon will merely be to observe, providing back-up to the anaesthetic staff in the (rare) event that tracheal intubation is not achieved. It is important, however, that ENT expertise is immediately available, as attempts to intubate the trachea may lead to increase swelling/inflammation and worsen airway obstruction. When ENT intervention is required, this may be to facilitate tracheal intubation via the oral route (e.g. use of an anterior commissure laryngoscope). In other cases, tracheostomy or cricothyroidotomy may be required. In cases where tumour or infection/abscess is the basis for the airway obstruction, resection/debulking of tumour or evacuation of an abscess cavity may be carried out after the airway problem has been resolved.

The second common clinical scenario is the late management of patients with continuing need for tracheal intubation. This is usually managed by tracheostomy. It should be remembered that since many tracheostomies are now performed as a bedside, percutaneous procedure, referral to ENT suggests the procedure is expected to be difficult, often due to anatomical factors or coagulation disorders. The indications for late tracheostomy is usually due to the need for prolonged tracheal intubation for the following reasons:

- failure (or predicted failure) to wean from mechanical intubation;
- lack of airway protection (bulbar palsy, cord dysfunction, coma);
- need for tracheobronchial toilet (decreased level of consciousness).

Assessment of cord function

In patients with problems concerning airway patency/stridor, inability to cough effectively or suspected

(repeated) pulmonary aspiration, ENT may be asked to rule out vocal cord dysfunction. This may be required after surgery on the thyroid, parathyroid or nearby structures when recurrent laryngeal nerve injury may occur. Some neck, mediastinal and apical lung tumours may also produce dysfunction of the recurrent laryngeal nerve. Assessment usually involves visualizing the cords (without neuromuscular blockade) either using a fibreoptic or rigid bronchoscope. The former may be carried out in ICU as a bedside procedure.

Investigation of source of sepsis

Attempts to identify an occult source of severe or recurrent sepsis is a common process in ICU. After exclusion of the usual sites by culturing blood/sputum/urine/cerebrospinal fluid (CSF), imaging the chest and abdomen and removing invasive lines, the question of sinus infection must be ruled out. Since most ICU patients have feeding and/or other tubes passing through the nasal passages, they are predisposed to retention and superinfection of sinus secretions. This may be particularly so after head and facial trauma when there may have been bleeding into the sinus cavities. In such circumstances, ENT services may be asked to perform antral lavage to provide material for culture and remove a nidus of infection.

SEVERE SEPSIS/SIRS

The triggering of the inflammatory response is designed to be (and usually is) protective. The usual trigger is invasion by microorganisms (infection) and is termed sepsis. However, tissue damage from trauma, burns or major surgery may also act as the trigger to this inflammatory response, in which case it is termed systemic inflammatory response syndrome (SIRS). Both SIRS and severe sepsis may lead to septic shock whose clinical manifestations include hypotension, tachycardia, pyrexia and warm flushed peripheries. The early cardiovascular changes can be summarized by stating that there is peripheral vasodilatation with an elevated cardiac index, low arterial pressure and low filling pressures. Younger patients with more cardiac reserve may well not become hypotensive due to their ability to substantially increase cardiac index. The criteria for SIRS, sepsis and severe sepsis are well established, as are the definitions of severe sepsis and sepsis with shock.⁵³

Management should include restoration of circulating volume, correction of tissue hypoxia and prevention of avoidable insults to organ function and has been well described elsewhere.^{54, 55} Good infection control policies and practices have been shown to reduce nosocomial infection rates.⁵⁶ Early treatment of sepsis with appropriate antimicrobial therapy has been shown to improve survival in critical illness.^{57, 58}

Resuscitation

The aggressive infusion of colloid and/or crystalloid under the guidance of central venous or pulmonary artery occlusion pressures will stabilize the condition in many patients. Should it prove impossible to attain an adequate blood pressure, then the problem is usually one of profound vasodilatation. In such cases a controlled infusion of a vasoconstrictor, such as noradrenaline or phenylephrine, may restore pressure and return coronary perfusion to normal. Vasoconstrictors are often used in conjunction with dobutamine to sustain cardiac contractility and general perfusion. When using noradrenaline in this way, it may be desirable to use a means of quantifying cardiac output and global perfusion (e.g. pulmonary artery catheter) to ensure that excessive vasoconstriction does not take place. Even this does not give any guide to the flow through regional capillary networks.

The guiding principles of haemodynamic manipulations in SIRS/solidus sepsis are:

- restore normovolaemia;
- commence dobutamine;
- use the smallest dose of noradrenaline which is compatible with acceptable blood pressure;
- augment cardiac contractility if required (e.g. dobutamine);
- check haemodynamic status by serial measures of arterial lactate and/or measurement of cardiac index.

Even with the above measures, a minority of patients remain grossly vasodilated, hypotensive and may die of refractory cardiovascular failure. Others improve haemodynamically with the above measures only to die later following the development of acute lung injury, renal dysfunction and other manifestations of SIRS/sepsis-induced multiple organ dysfunction syndrome (MODS).

Antimicrobials

Antibiotics should be administered as soon as possible. At this point the nature of the microorganisms concerned is unknown. Therefore, it is common currently standard practice to use double or even triple antibiotic therapy to cover all possible causative organisms. Fungi should not be forgotten as possible causative agents, especially in patients who have been on long-term broad spectrum antibacterial agents. The next step is to identify and remove potential sources of sepsis. Wounds should be examined and probed if necessary. All intravascular lines and the urinary catheter should be changed.

Investigating the source of infection

The source of sepsis is often obvious. In other cases, however, full examination fails to reveal a problem. This

group of patients needs persistent investigation. Initial cultures should be taken from blood, sputum, urine, CSF and any surgical drains, if possible before the administration of antibiotics. A chest x-ray may reveal any pulmonary infection and/or the presence of fluid in the pleural cavity. If the latter is present, then a diagnostic tap and/or drainage via a chest drain will be necessary. If cultures, x-ray and clinical examination are unrewarding, the location of an occult source of sepsis may lie in the abdominal cavity (including the pelvis) or the intracranial space or the paranasal sinuses.

These possibilities can be narrowed further by ENT endoscopy or double antral punctures and lumbar puncture. The abdominal cavity can be assessed noninvasively in several ways using ultrasound scan, CT scan or labelled white cell scan. After all three of these investigations have been performed and repeated, there should be an 80 percent 'pick up' rate for septic foci within the abdomen/pelvis.⁵⁹ Once located, a septic focus may be obliterated either by radiologically guided percutaneous drainage or by surgical laparotomy. There is still an indication for the investigative laparotomy which will occasionally find a lesion previously missed by other forms of investigation. Laparotomy may need to be repeated after an interval before all sources of sepsis can be excluded.

RECENT EVIDENCED-BASED STRATEGIES IN CRITICAL CARE

Rigid glycaemic control

Hyperglycaemia is commonly associated with critical illness and has been considered an adaptive response to ensure an energy source for brain cells and erythrocytes. However, high titres of insulin-like growth factor binding protein 1 are associated with decreased insulin production and increased mortality.⁶⁰ The use of insulin infusion in over 1500 (mainly surgical) ICU patients to maintain blood glucose in the (low) normal range (4.4–6.1 mmol/L) showed a significant benefit over conventional treatment (mortality rates of 4.6 and 8.0 percent, respectively).⁶¹ This benefit was most pronounced with prolonged ICU stay (≥ 5 days). Although this effect might have been due to other effects of insulin, e.g. on plasma free fatty acids, further work has suggested control of blood glucose and not the dose of insulin used, was the factor conferring survival advantage.⁶²

Target haemoglobin levels/blood transfusion

Anaemia is common in critical illness for many reasons, including a blunted erythropoietin response to acute anaemia.^{63, 64} The first issue is whether or not this anaemia is harmful? Studies would indicate that moderate anaemia

is potentially beneficial^{65, 66} and that red cell transfusion to maintain a higher than necessary level of haemoglobin may be detrimental.^{67, 68} What is unclear is whether the harmful factor is a relatively higher level of haemoglobin or the transfusion of donated stored allogeneic blood. While exogenous erythropoietin has been shown to reduce transfusion requirements and result in increased haemoglobin concentration in critically ill patients,⁶⁹ we should not assume that this will necessarily lead to improved outcome.

We need to develop appropriate triggers for transfusion which maximize the potential advantage of anaemia and also reduce the need for allogeneic red cell transfusion with its well-known risks. Other strategies, such as use of blood conservation policies or devices, should be investigated,⁷⁰ although there is little evidence to date that the latter are effective.^{71, 72}

Early goal-directed therapy

The underlying principle of early goal-directed therapy (EGDT) is that the early resuscitation of patients with severe haemodynamic compromise may be incomplete if blood pressure is used as the end-point (see under Cardiovascular support above). This may leave many patients with 'normal vital signs' but occult shock with ongoing tissue hypoperfusion/hypoxia and increased risk of subsequent organ failure. The EGDT approach uses fluid/blood transfusion and dobutamine and perfusion related parameters as the end-points of resuscitation. Specifically, central venous oxygen saturation (ScvO₂) is monitored via a central venous line. EGDT commenced in the emergency room has been shown to reduce mortality in patients with severe sepsis.⁷³

Low tidal volume ventilation

Excessive positive pressure and/or lung stretch has been linked to VILI as discussed under Respiratory support. This may be due to production of inflammatory mediators promoted by use of higher tidal volume ventilation.^{74, 75} Clinical studies have suggested that limiting the tidal volume and/or the ventilatory pressure improves outcome in patients with acute lung injury.^{76, 77} Hence, there is an increasing tendency to use low tidal volume (6–8 mL/kg) rather than the more traditional 10–12 mL/kg for MV in critical illness. However, methodological differences⁷⁸ mean it is difficult to compare studies and some work suggests increased morbidity and poorer outcome with a low tidal volume/low inflation pressure strategy.⁷⁹

Activated protein C

Sepsis, decreased protein C levels and high mortality have been linked,^{80, 81} while infusion of activated protein C has

been shown to improve survival in animals infused with live coliforms.⁸² Use of recombinant human activated protein C (APC) in severe sepsis has been shown to achieve an absolute reduction in mortality of 6.1 percent and has an even greater benefit in those patients with associated multiple organ failure (absolute mortality reduction 7.4 percent).⁸³ Although the anticoagulant, profibrinolytic and antiinflammatory (reduction in IL-6) actions of APC are known, its beneficial effects in severe sepsis are still not fully explained.

Steroids

Critical illness can unmask and even cause a relative failure in adrenal function. The adrenal gland is vital in the adaptive response to critical illness. It produces glucocorticoids (cortisol) and mineralocorticoids from the cortex of the gland and catecholamines from the medulla. It is common in ICU to use catecholamines to support the circulation. However, glucocorticoids are often avoided because of their side effects and so unrecognized adrenal dysfunction may lead to life-threatening cortisol deficiency. Predisposing factors include major surgery, trauma, coagulopathy, but particularly severe sepsis.⁸⁴ The clinical manifestations of the condition are hypotension unresponsive to treatment and other relatively nonspecific findings such as electrolyte abnormalities (hyperkalaemia, hyponatraemia) and generalized weakness which are common in the ICU population.

Although investigation of the use of steroids in severe sepsis has produced well over 100 papers, there have been few methodologically rigorous studies.⁸⁵ Relative adrenal insufficiency may exist in ≥ 50 percent of patients with septic shock which is refractory to inotropic support.⁸⁶ Patients with sepsis exhibit reduced plasma cortisol binding and decreased glucocorticoid receptor binding.^{87,88}

Two studies seemed to confirm that moderate doses of steroid in patients with septic shock improved responsiveness to catecholamines.^{89,90} This prompted a multicentre French trial using a seven day course of moderate dose (200–300 mg/day) hydrocortisone and fludrocortisone in patients whose adrenal function was assessed using an ACTH stimulation test.⁹¹ Relative adrenal insufficiency was found in 229 of 300 subjects. In this subgroup, 115 received steroids and 114 placebo. The mortality rates were 63 and 53 percent, respectively ($p < 0.023$). In ACTH responders, steroids had no survival advantage, nor excess attributable mortality. A subsequent cross-over study showed hydrocortisone restored haemodynamic stability in critically ill patients with septic shock and promoted an antiinflammatory, but not immunosuppressed, state.⁹² Diagnosis of relative adrenal insufficiency requires a high index of suspicion and blunted response to an ACTH or Synacthen stimulation test.⁸⁴ Treatment is by steroid replacement during the stressed period – 100 mg of hydrocortisone six hourly is a widely used regime.

END OF LIFE ISSUES

Communication with relatives

Critical care patients are often unaware of their ICU stay until they are almost ready for discharge. Their relatives often bear a heavy emotional burden, their degree of confusion and helplessness made greater by the complexity and the seriousness of the clinical situation. This may be compounded by the numbers of doctors, nurses and clinical teams involved and the length of time the patient may remain in a life-threatening state. It should be remembered that even a short 'routine' admission to ICU is one of the most stressful events ever experienced by most families.

Relatives' stress can be reduced by reducing the number of staff through whom they receive information. Interviews with relatives should occur in a quiet, private and comfortable counselling room adjacent to the ICU. An individual's interpersonal skills and personality will have a significant influence on their approach and success in counselling relatives. The experience of others, however, can give valuable lessons. These include:

- always sit down when talking to relatives (this may mean sitting on the floor when dealing with a large family) otherwise you may appear unfriendly or in a rush;
- always introduce yourself and any other accompanying member of staff. If possible, bring the patient's bedside nurse;
- know before you enter the room who will be there and their relationship to the patient;
- check the patient's name (including first name), age and address. Remind yourself of the date of hospital and ICU admission and other details of the case. It is advisable to have the clinical notes with you;
- start your delivery with a question such as 'Before I update you, can I ask what *you* understand the position to be?' This achieves several goals. You find out what is already known. You will therefore be able to judge whether the family are inappropriately optimistic or pessimistic. They will focus on the issues which they feel are important or which most worry them. This will allow you time to tailor your information to bring them up to date and (hopefully) correct any misconceptions. You are also able to judge the degree of understanding within the family and the level at which to pitch your discussion.

In cases involving multiple clinical teams there is an increased danger of families receiving 'mixed messages' and being further distressed and confused. It may be helpful, at an early interview, to point out that each clinician involved will tend to focus on their own particular area/role and that the ICU staff are in the best position to give an overall view of the patient's condition and short-term prognosis.

Limitation of treatment

Limitation in this context means to either withhold or withdraw one or more treatments from a patient – presumably because in the view of those clinicians making such a decision, the treatment(s) are not in the patient's best interest. In ICU, this usually means that the patient has no prospect of survival (irrespective of the treatment offered) or that survival would be unacceptable (in terms of quality of life). The latter needs to be considered very carefully since quality of life is a subjective judgement. Although withholding or withdrawing treatment do not differ ethically, some feel that withdrawal is more difficult as the cessation of treatment appears to be more closely associated with death than withholding, when the progression of disease appears to cause the death of an individual. The opposing view is that having started a treatment and then withdrawn it, we are in a better position to know that it was a futile intervention and one which was not going to alter outcome.

Potential difficulties arise because of the clash of ethical and legal principles, medical policies and the emotional responses of both relatives and ICU staff in a situation where the views of the patient are often unknown and unobtainable. Such problems are always more difficult in the ICU environment where many kinds of organ support are made possible by medical technology. Mostly, such interventions are totally appropriate. Occasionally they are obviously inappropriate. However, it is when there is disagreement on appropriateness of treatment that problems may arise and a structured approach to decision making is required.⁹³

Although limitation of treatment is common in ICU,⁹⁴ doctors, nurses and the public differ in their view of who should have input into such decisions.⁹⁵ Doctors and nurses in ICU may also disagree on how to conduct end-of-life decision-making and who should be involved.⁹⁶ If limitation of treatment is to be acceptable in ICU, the conduct surrounding such orders (often termed do not resuscitate (DNR) orders) should adhere to the following.

- DNR orders should be made in concert by several of the most senior ICU clinicians. The process should include consultation with other members of the ICU team. The views of the next-of-kin should be sought but it should be made clear that they are not being asked to make the decision.
- Such decisions should be indicated by a written, unambiguous entry in the patients clinical notes.
- The relatives and other clinical services involved should be informed of the decision before it is initiated.
- The decision should be reviewed and (if appropriate) renewed every day.

Effective communication and a caring and open approach will prevent and/or resolve many of the problems which may arise in an 'end-of-life' situation.

SEARCH STRATEGY

Data for this chapter are mostly generic management strategies for children in intensive care. The data were gathered through reference to standard texts on paediatric intensive care, notably *Textbook of pediatric intensive care*¹ and *Fluid balance and volume resuscitation for beginners*.² Specific information on ENT trauma in children was obtained through PubMed using the key words laryngeal trauma and laryngeal injury, limiting the search to children 0–18. This revealed 65 review articles of which five were found relevant and scrutinized. Information on bronchoscopy was located on PubMed using the key words fiberoptic bronchoscopy and intensive care, limiting the search to children 0–18. This only yielded two papers (one from 1980), but searching on the related links button located a number of relevant articles.

INTRODUCTION

Children are liable to present acutely with ENT pathologies, many of which are specific to the paediatric population and may require intensive care management. Those children undergoing major ENT surgery also frequently require admission to a paediatric intensive care unit in the postoperative period. This chapter aims to outline the general management principles of ENT patients within the paediatric intensive care setting. Important differences in the anatomy and physiology of children compared to adults are reviewed. A systematic approach to evaluation of children admitted to the paediatric intensive care unit (PICU) is outlined, together with general principles of fluid and analgesia management in children. Specific issues relating to the care of the major paediatric emergencies, as well as the postoperative management of patients undergoing major ENT surgical procedures, are discussed. Finally, indications and

procedures for performing bronchoscopy within the unit are detailed.

GENERAL PRINCIPLES

Anatomical and physiological considerations

Care of the paediatric patient requires an understanding of the anatomy and physiology of children, which have some important differences from adulthood.

Anatomically, the child has quite different body proportions and shape. The head of the infant and small child is proportionately larger, accounting for nearly 10 percent of body surface area, compared to the 3.5 percent in adults. The neck of a child is shorter, and these two factors tend to increase neck flexion, particularly in the emergency setting. A relatively large tongue and small mandible can make access to the airway difficult.

Table 43.1 Physiological parameters at different ages.

Age	Heart rate (bpm)	Respiratory rate (bpm)	Mean BP (mmHg)
Newborn	110–140	50–60	50–60
1 year	90–110	30–40	70–90
2–5 years	75–90	25–30	80–100
5–12 years	60–90	20–25	90–110
>12 years	50–80	15–20	100–120

In all young children the epiglottis is rounded ('horseshoe shape') and the larynx sits high (opposite the third cervical vertebra, compared to the fifth or sixth in an adult) and anterior. The larynx itself is conical, unlike the cylindrical adult larynx, and the narrowest part lies at the cricoid cartilage. Finally, the tracheal cartilage is often less rigid than in adults, and may compress if the neck is overextended.³

Infants (up to approximately six months old) are also obligate nasal breathers. When this is combined with the relatively small airways and risk of mucous obstruction, airway compromise is common. Between three and six years of age, tonsillar and adenoidal hypertrophy further contribute to airway obstruction.

Physiologically, there are also substantial and important differences. Respiratory muscle function is affected by the position of the ribs in infants, which lie perpendicular to the spine rather than running caudally as they do in adults. This makes the diaphragm the only effective inspiratory muscle. Infants and children have a faster respiratory rate than adults (see **Table 43.1**), which is partly related to an increased metabolic rate. In infants, increased chest wall compliance can increase the work of breathing substantially.

In the cardiovascular system, a limited stroke volume causes a faster heart rate in children, and they also display a lower mean blood pressure. Their response to cardiovascular stress is limited, and cardiac output can only be increased significantly by increasing the heart rate, hence tachycardia is common.

Evaluation

Admission of a child into the PICU is a difficult and important moment in the child's care. The care of the child is transferred to a new team of doctors and nurses, and the family are moved to a new and stressful environment. It is essential that this handover is careful and complete. Ideally, there should be a face to face handover between the medical and nursing teams involved in the care. The background history, current problems and care plan should be clearly documented.

The family of the child need to be included in this handover. Where the admission is planned, families

should be offered the chance to visit the intensive care unit prior to the surgery so that they have met some of the staff and seen the environment. There should be an area for them to stay in while procedures are being carried out and they need regular updates from medical and nursing staff on progress.

The doctors admitting the child also need to evaluate the child carefully on admission. This should follow standard 'ABC' rules, assessing the airway, breathing and circulation. Issues of fluid balance (including any feeding plan), analgesia, sedation and blood tests should also be clarified (**Table 43.2**).

Fluid management

Although the principles of fluid balance in children are the same as in adults, there are a number of complicating factors that make life more difficult for the junior doctor. The first and most obvious is an unfortunate tendency for children to grow! Any fluids that need to be given are therefore based on the child's weight or occasionally the body surface area. Metabolic requirements, including insensible water loss, vary with age and this must be taken into consideration.

The distribution of fluids between compartments is different for adults and children, and an understanding of this difference is important in deciding on appropriate volumes and types of fluid. The infant has approximately one-third of their body weight as interstitial fluid – twice as much as in an adult. Consequently, fluids constitute approximately 75 percent of body weight in infancy, compared to 60 percent in the adult.

THE NEWBORN INFANT

The full-term infant requires approximately 150 mL/kg per day of fluid (although less in the first few days of life). Of this, approximately 30 mL/kg will be accounted for by insensible losses. Normal fluid intake is entirely as milk, which provides both fluid and nutrition for the first few months of life. Fluid requirements (per kg) gradually

Table 43.2 Issues to be considered on admission of a child to PICU.

Issues to consider	
Airway	Clear? ET tube position? ET tube secured properly?
Breathing	Air entry? Ventilation adequate?
Circulation	Peripheral perfusion? Adequate access?
Fluids	Drug infusions? Adequate sugar? Urine output?
Analgesia/sedation	Pain control AND sedation adequate? Paralysis needed?
Tests	Blood gas? Electrolytes? FBC?

Table 43.3 Fluid and electrolyte requirements at different ages.

Age	Daily fluid requirements	Sodium/potassium requirements
1 day	60 mL/kg	2–3 mmol/kg/day
5 days	150 mL/kg	2 mmol/kg/day
1 month	120 mL/kg	1–2 mmol/kg/day
6 months	110 mL/kg	
1 year	100 mL/kg	
Over 1 year	1000 mL for first 10 kg, 500 ml for next 10 kg then 20–25 mL/kg for rest of body weight	

reduce thereafter, as shown in Table 43.3. It should be emphasized that these requirements are based on normal needs and that they frequently need adjustment in disease.

Electrolyte requirements will also vary with age, although not so dramatically as fluid volume. In the infant, immature renal function increases the salt requirements, and 3 mmol/kg of sodium and potassium are usually required daily. In older children this falls to approximately 2 mmol/kg/day of each ion. Calcium, magnesium and other ions are broadly given in the same (per kg) dose as in adults.

Glucose requirements are critical, especially in young children. The daily calorie requirement of infants is approximately 100 kcal/kg, more than double that in adults. Maintenance of adequate glucose levels in infants is critically important and hypoglycaemia (even for short periods) can cause permanent brain damage. In infants and small children, enough glucose must be given to maintain blood glucose levels.

THE UNWELL CHILD

Fluid requirements following surgery can be quite variable. In most units, children are started on a regime restricting their input to approximately two-thirds normal requirements. This is especially true if oral feeds are not to be used and fluids are being given intravenously. Intravenous fluids should be chosen with care. Recently, concerns have been raised about the use of hypotonic fluids (especially 0.18 percent saline) as this tends to induce hyponatraemia which can cause substantial problems including seizures and indeed death.^{4,5} Solutions containing adequate sodium (such as 0.45 percent saline, 2.5 percent dextrose) are therefore recommended. Whatever regime is used, it needs to be remembered that children are prone to become dehydrated or fluid overloaded quite rapidly and need to be monitored carefully. In infants especially, blood glucose levels need to be measured regularly (up to four hourly). [**/*]

Analgesia

Appropriate analgesia needs to balance the sedative and respiratory suppressive effects of opiates against the need for good pain control. Oral paracetamol, or other nonsteroidal antiinflammatory drugs (NSAIDs) may often be adequate, but opiates (e.g. morphine) may be needed. An infusion (e.g. morphine at 10–30 µg/kg/hour) is easily administered. In older children, patient controlled analgesia (PCA) pumps are helpful. Background rates (e.g. morphine at 10 µg/kg/hour) with boluses as needed (e.g. morphine 10 µg/kg up to hourly) is often a good combination but should be discussed with the anaesthetist involved. Sedation may also be needed for patients in the PICU, especially if ventilated or undergoing painful procedures. Units vary between using infusions (e.g. midazolam 50–250 µg/kg/hour) or boluses (e.g. midazolam 0.1 mg/kg, p.r.n. up to four hourly). Current trends favour intermittent bolus dosage as this reduces total sedative load, but patients need close observation to avoid distress. [*]

ENT EMERGENCIES IN PICU

Trauma

All trauma cases, including those who have sustained craniofacial trauma, should be managed acutely according to advanced life support guidelines,³ with immediate evaluation and management of airway, breathing and circulation. Cases of blunt laryngeal trauma are rare. They may occur if a child is unrestrained in a car involved in a road traffic accident if they hit the dashboard when the head and neck are in a hyperextended position. In children presenting with laryngotracheal injuries in the absence of such a history, the possibility of nonaccidental injury with a direct blow to the anterior neck should be considered as a possible aetiology.

A protocol for the management of acute laryngeal trauma was devised and published by Schaefer in 1982.⁶ This advocates immediate protection of the airway by emergency tracheostomy for all but the most minor of cases, with endoscopy to evaluate the injuries. In patients with moderate injuries, the degree of traumatic damage can be further assessed using CT scanning once the airway has been protected by tracheostomy. In cases where the injuries are severe, open exploration is recommended. [**/*]

Upper airway obstruction

The small cross-sectional area and conical shape of the paediatric airway renders children particularly susceptible to upper airway obstruction. A relatively small reduction

in the radius of the airway through mucosal oedema, secretions or a foreign body, results in a significant increase in airway resistance (resistance \propto diameter).⁶ Stridor on inspiration is indicative of upper airway obstruction. In children where severe upper airway obstruction is suspected as a diagnosis, it is imperative to avoid all invasive procedures and aspects of the examination liable to distress the child as this may precipitate complete upper airway occlusion. Children should be kept warm and calm while experienced anaesthetic and surgical staff are brought together. Examination can then be undertaken in a controlled manner. A full examination of the child is also needed at a convenient point. Birthmarks, and especially haemangiomas (which may indicate a laryngeal lesion), should be recorded. If a child is dysmorphic, a genetic opinion may help identify a syndrome that may have airway implications.

EPIGLOTTITIS

The advent of the Hib vaccine and its inclusion in childhood immunization schedules to protect them against *Haemophilus influenzae* type B infections, has led to a marked decline in the incidence of epiglottitis so that it is now a rare condition. However, occasional cases do still occur in unimmunized children or in those in whom the vaccine has failed. Clinical presentation is with a toxic child who is stridulous and drooling.

The priority of immediate management is to secure the airway by intubation or, in extreme cases, emergency tracheostomy. They will then remain ventilated in intensive care whilst receiving treatment with intravenous antibiotics (third generation cephalosporin) until the epiglottic swelling has been reduced, usually within 24–36 hours.⁷ [*]

CROUP

Acute viral laryngotracheobronchitis (viral croup) is the most common cause of stridor in children and the vast majority of patients can be managed either at home or on the general paediatric wards. Only the most severe cases require admission to a high dependency unit (HDU) or PICU.

In such cases, short-term relief of the upper airway obstruction can be achieved by nebulizing epinephrine (1 mL/kg of 1:1000 up to 5 mL maximum dose) with oxygen. Steroids, either in the form of nebulized budesonide or systemic dexamethasone or prednisolone, can be given to reduce the upper airway inflammation. A very small minority of children with croup require intubation to protect their airway (<5 percent), but the administration of systemic steroids to this group of patients has been shown to reduce both the duration of intubation and the need for reintubation (Table 43.4).⁸

Table 43.4 Features of croup versus epiglottitis.

	Croup	Epiglottitis
Age	1–3 years	2–7 years
Cause	Parainfluenza viruses	<i>H. influenzae</i>
Prodrome	1–2 days coryza	Hours
		Sore throat
		Dysphagia
Fever	<38°C	>38°C
Appearance	Lethargic	Pale and toxic
		Drooling and dysphagic
		Sits with neck extended
Stridor	Barking cough	Muffled stridor
	Loud stridor	Stertorous breathing
Hypoxia	Unusual	Frequent
Severity	<3% hospitalized cases	All require intubation
	require intubation	

In all children with stridor, the consideration of other diagnoses, such as a postpharyngeal abscess, needs to be undertaken. [****/***/**/*]

Bacterial tracheitis

Bacterial tracheitis, or pseudomembranous croup, is much less common than viral croup but it is potentially life threatening and the majority of patients will require intubation to secure their airway whilst receiving treatment with intravenous antibiotics. The pathogens are usually *Staphylococcus aureus* or *Streptococci*, which infect the tracheal mucosa causing necrosis and the production of purulent secretions that may occlude the upper airway. Clinically, a child with bacterial tracheitis is septic with a high fever, croupy cough and progressive signs of upper airway obstruction.

Foreign body inhalation

A history of possible foreign body inhalation can usually be elicited, but in the absence of such information it should be suspected as a cause if there is sudden onset of stridor and upper airway obstruction with no history of preceding fever or illness. It occurs most commonly in children between the ages of one and three years, with foodstuffs being the usual cause.

In such cases, if the child presents with increasing dyspnoea, apnoea or loss of consciousness which has not responded to simple airway opening manoeuvres, then the advanced paediatric life support guidelines for management of a choking child should be instituted.³ In an older child the Heimlich manoeuvre can safely be attempted or, if the child is unconscious and supine,

abdominal thrusts may be equally effective at dislodging the foreign body.

The foreign body may in some cases pass through the larynx and become lodged lower down in the bronchial tree. As discussed earlier, the larynx in the prepubertal child is conical, and objects passing the vocal cords can lodge at the level of the cricoid.³ It is essential that one does not use blind finger sweeps in the mouth for the foreign body as this may push it tighter into the larynx.³ Objects may also pass right into the lungs. On clinical examination there may be unilateral wheezing, reduced air entry on one side or signs suggestive of unilateral lung collapse. A chest x-ray may show hyperinflation of the affected lung with mediastinal shift due to the foreign body causing gas trapping on expiration, or alternatively lung collapse. These patients require a general anaesthetic for rigid bronchoscopic removal of the foreign body and may need a period of ventilation on the PICU afterwards. [**/*]

MAJOR SURGERY

Craniofacial surgery and cleft lip and palate

Children who undergo craniofacial surgery or a cleft lip or palate repair, may require admission to a PICU or HDU, particularly if there is a risk of the airway becoming compromised by postoperative swelling. If the child returns from theatre ventilated, sedation and analgesia need to be maintained for the whole period of ventilation. A partially sedated child may struggle with an endotracheal tube (ETT) *in situ*, and this may damage a palatal or laryngeal repair. It may be necessary to paralyze the child once they are adequately sedated. This is often best carried out with short-acting anaesthetic agents, particularly when there is a planned extubation, as this will allow the child to be woken promptly. With longer-acting drugs there may be accumulation of the drug, and a period of suboptimal sedation/wakefulness as it is metabolized.

Other important considerations include the use of orogastric rather than nasogastric tubes, best sited under direct vision at the time of the operation, as nasogastric tubes can traumatize a palate repair. Nursing staff should be aware not to perform blind oropharyngeal suction with a rigid Yankaeur sucker, but should use a soft wide bore flexible suction catheter to remove visible secretions only. Infection, particularly with streptococcus, can be devastating to palatal repairs. As well as careful nursing and cleanliness, patients should not be nursed close to other children who may be carrying pathogens. [*]

Surgery of the nose and upper airway

Patients who have surgery to the nose rarely require an admission to PICU in the postoperative period. If they do,

then the general principles of evaluation and management should be applied. The exception may be with infants who require surgery for choanal atresia/stenosis. In these children, maintaining a patent nasal stent may require close nursing observation for the first few days.

Those undergoing surgery to the upper airway are, however, frequently admitted to PICU for a period after the operation due to the high risk of developing upper airway obstruction as oedema evolves around the site of surgery. This includes operations for laryngeal reconstruction, but also for more minor procedures such as aryepiglottoplasty. It is therefore important to ensure that a PICU/HDU bed is available for the patient before proceeding with surgery. Children who have major upper airway surgery, such as laryngotracheal reconstruction, are electively ventilated for a period of five to seven days after the operation to allow the oedema to resolve before the ETT is removed. In these patients, sedation and analgesia are again critical (see Craniofacial surgery and cleft lip and palate). Paralysis is usually used in this patient group to prevent trauma to the site of surgery and exacerbation of upper airway oedema due to movement of the ETT whilst *in situ*. Close observation of cardiovascular parameters in paralyzed patients will detect tachycardia and hypertension suggestive of inadequate sedation or pain underneath the paralysis. It is important that a significant leak is allowed to develop around the ETT before extubation is attempted as this may signify that the postoperative oedema is resolving and that extubation is more likely to be successful. [*]

Laryngeal surgery and tracheostomy

Managing a tracheostomy in the PICU involves the management of the newly formed stoma, care of an established tracheostomy and training requirements for families looking after long-term tracheostomies.

In the first week after a tracheostomy is formed, the airway is dependent on the tracheostomy stent (i.e. the tube) to maintain the airway open. Loss of the stent over this period can allow the airway to close, and the reinsertion of a tube through an immature tracheostomy can be difficult, as the tracheal opening can be obscured (especially in obese patients) and the tube can easily be passed into the wrong plane. This results in obstruction of the airway and ventilation of the tissues of the neck. For the first week, a new tracheostomy should therefore be carefully secured. In our unit, stay sutures are attached to the edges of the trachea at surgery, allowing the trachea to be brought up to the surface of the neck in an emergency and thus facilitating tube reinsertion.⁹ A tracheal dilator and spare tracheostomy tubes (of the same size and one size smaller) should be kept at the bedside.

If a tracheostomy tube does become dislodged in this period and cannot easily be reinserted, then (assuming the larynx permits this) a conventional endotracheal tube

should be put in through the mouth or nose to secure the airway. This allows a measured replacement of the tracheostomy tube either in the PICU or in theatre.

Following the first tracheostomy tube change (usually at seven to ten days), the tracheostomy is more secure. Care of an established stoma involves the establishment of routine tube changes, tape care and training for the carers (where appropriate). The development of difficulties with tube insertion or of bleeding should raise the possibility of granulation formation.

Parents who are to go home with a child who has a tracheostomy will need careful training. As well as confidence in tube and tape changes, training in resuscitation is necessary, as is an ability to perform adequate tracheal suction. Preparation of equipment and provision of support at home may take many weeks to organize. [*]

Bronchoscopy in PICU

FIBREOPTIC BRONCHOSCOPY

This is a very useful technique, as it is extremely simple to pass a fibreoptic scope through an ETT and directly into the lung. Its advantages include simplicity and access. The scope can visualize all lobes of the lung and identify both static (e.g. mucous plugs) and dynamic (e.g. bronchomalacia) problems. The disadvantages include a narrow suction channel that blocks easily, and the inability to effectively ventilate through the scope. The latter can be circumvented if the scope is passed through a rubber valve in the ETT, allowing continued ventilation around the scope, but is difficult if the diameter of the scope is close to that of the ETT.

RIGID BRONCHOSCOPY

This technique is much more effective at removing debris from the airway, and may be easier to use in the very unstable patient as ventilation can be continued through the scope during the procedure.

There are several indications for either fibreoptic or rigid bronchoscopy in PICU:

- *Persistent collapse of lobe/lung.* Ventilated children may develop complete collapse of a lung, usually secondary to blockage of the major airways with secretions and mucous plugs. This can lead to major ventilatory problems with shunting. Fibreoptic bronchoscopy down the ETT can often identify the degree of blockage but a rigid bronchoscope may be needed to clear thick secretions.
- *Assessment of malacia.* Clinical tracheo- or bronchomalacia may be difficult to confirm. Flexible bronchoscopy may help locate the site and degree of weakness, but needs to be carried out with the patient self-ventilating as positive pressure ventilation can stent the airway open artificially.

- *Assisted intubations.* In particularly difficult airways, a flexible bronchoscope or laryngoscope can be extremely useful in locating the airway. By threading an ETT over the scope prior to entering the airway, the ETT can then be placed into the correct position.
- *Collection of bronchoalveolar lavage fluid.* In patients who develop severe lung disease, and particularly in patients who are immunosuppressed, the diagnosis of lung pathogens can be very difficult. Bronchoalveolar lavage may be very useful in this situation. It can either be carried out 'blind'¹⁰ by passing a nasogastric tube into the lungs, washing in a small volume of 0.9 percent saline, and then aspirating, or using a fibreoptic scope to direct the lavage to a particular part of the lung. [**/*]

SUMMARY

Whilst principles of care for children are similar to those of adults, there must be careful consideration of the different physiological responses seen in children and how they vary with age. Some ENT procedures are also very specific to the younger age group, and in units which are not undertaking paediatric surgery frequently, well maintained guidelines for the care of this group of patients is essential.

KEY POINTS

- Foreign body inhalation should be suspected in any child with unexplained stridor or respiratory symptoms.
- Paediatric anatomy and physiology is significantly different from adults.
- Fluid and electrolyte prescriptions for children must be adapted to the individual and calculated according to weight.
- Frequent monitoring and adjustments of fluid and electrolyte prescriptions are required.
- All patients with suspected epiglottitis require intubation.
- Trauma and infection are the greatest threats to palate repairs.
- Good evidence to support clinical practice in the PICU is limited.

Best clinical practice

General Principles

- ✓ Anatomical and physiological differences between adults and children need to be recognized.

- ✓ Fluid and electrolyte administration must be age- and weight-appropriate.
- ✓ Appreciation of family carers and their involvement is essential.

ENT emergencies in PICU

- ✓ Laryngeal trauma in children usually requires a tracheostomy.
- ✓ Epiglottitis is now rare in the UK following the introduction of the Hib vaccination.
- ✓ Foreign body inhalation is an important, if uncommon, cause of acute respiratory symptoms in children.

Major surgery

- ✓ Paralysis may be needed following palatal surgery to avoid damage from a struggling child.
- ✓ Infection is a major cause of palatal breakdown in children following surgery.
- ✓ Flexible bronchoscopy in children can clear secretions, but the size of the bronchoscope limits its suctioning ability.
- ✓ Suspected foreign bodies should be removed through a rigid bronchoscope.

Deficiencies in current knowledge and areas for future research

Many of the clinical practices on PICU have evolved through sharing of experience rather than being substantiated by medical evidence or clinical trials and the potential for research projects aimed at providing evidence to support or refute current practices is huge. However, in reality there are significant practical limitations to undertaking such research, for example the ethics of research in children, difficulties in obtaining parental consent for entry into trials, and recruiting sufficient numbers of patients to achieve adequate power. Much of current research focuses on establishing optimal sedation and analgesia regimes for intensive care patients.

Continuing professional development and the		surgeons	556
maintenance of skills	553	References	558

INTRODUCTION

Over the past 20 years, surgical practice has changed almost beyond recognition. Ear, nose and throat (ENT) surgery, and particularly rhinology and rhinological surgery, are excellent examples of this. The technical aspects of surgery have changed as the materials, investigations and instruments available have evolved. Techniques have radically changed as completely new approaches have developed.

A simple illustration of this is the use of rigid endoscopes in nasal and sinus surgery, both for diagnostic and therapeutic purposes. Prior to the mid-1980s, almost all sinus surgery was undertaken using a headlamp. At that time, the illumination was relatively poor and access to parts of the nose and sinuses restricted. In the 1980s, a number of surgeons started to see the benefit of using the illumination and magnification of the operating microscope to deal with sinus disease. However, within a few years rigid endoscopes became increasingly available and in less than ten years entered widespread use in the USA, UK and Europe. This change from relatively crude surgery to accurate dissection, based on ever-improving imaging and now image-guided systems, has entirely changed our knowledge and practice.

The concepts that underpin our understanding of sinus disease have changed. A far greater emphasis is placed on medical, allergic and immunological aspects, as well as the relationship between the upper and the lower airway.

The transition described above has not been without problems. In both endoscopic sinus surgery and laparoscopic surgery, overenthusiasm for the method with

inadequate training has led to serious adverse outcomes. The need for structured training was recognized even for experienced surgeons. This change in technology and the rapidly expanding availability of computerized tomography (CT) scanning, giving the surgeon far more information about what they could expect to find anatomically and pathologically in the sinuses, has driven a need for on-going training for established practitioners and new curriculum for trainees. The Hill Surgical Workshop at the Royal College of Surgeons was one response to this need.

Surgeons today, both trainees and experienced, have to continue to acquire substantial new knowledge, new diagnostic skills and new technical skills throughout their career. We, as surgeons, have a duty to do this.¹

All these technical matters need to be seen within the broader context of change. The public, patients, legislators, healthcare professionals and the Government have all started to voice 'needs' within the healthcare system. Public confidence was shaken by the actions of Dr Shipman and the apparent lack of scrutiny of them.² 'Disasters', such as the cases highlighted in Bristol, where well-meaning surgeons fell below an acceptable standard, and the subsequent reports and inquiries have heightened the public taste for scrutiny of the medical professions.³

Patients, in general, want to be fully informed before consenting to a surgical procedure and we as surgeons are bound by the requirements of *Good surgical practice* to obtain informed consent.⁴

The issues surrounding consent are in themselves highly complex and outside the scope of this chapter, but highlight yet another change. A good doctor–patient relationship is a fundamental part of the care of a surgical

patient. Some surgeons have an innate 'skill' of communication, others simply do not. Attention to this aspect of the surgeons overall ability is now well recognized and is assessed and examined in both the MRCS and Inter-collegiate FRCS examinations. Good hand-eye coordination is not sufficient to make a modern surgeon.

The Royal College of Physicians and Surgeons of Canada published a substantial document in 1996 subtitled 'Skills for the new millennium' in which seven 'roles' were described as being important in a medical practitioner.⁵ The precise mixture of the roles and the extent to which they are relevant will vary from specialty to specialty and will be dependent on the stage of development of the practitioner, but to some extent all roles will be relevant to some degree in every practitioner. The roles defined are:

- medical expert;
- communicator;
- collaborator;
- manager;
- health advocate;
- scholar;
- professional.

Methods of evaluating these areas are also suggested.

The role of medical education, training and revalidation can be seen as a broad development of various roles largely defined by (though not exclusively) the list above.

EAR, NOSE AND THROAT SURGICAL TRAINING IN THE UK

Historic perspective

Until the mid-1990s, surgical training in the UK, and largely in those countries associated with the Commonwealth, had been based on an apprenticeship model. This tradition has assumed that over time the apprentice (young surgeon) would:

- acquire knowledge relevant to their particular specialization;
- develop clinical skills;
- gain exposure to conditions and diseases and understand their natural history and standard treatment;
- see complications and their resolution.

Over time, the novice would gain experience, skill and knowledge to ultimately master his or her specialty. The range of skills and knowledge acquired would be tested by examination and in-training assessment. In the UK, this individual would then progress to positions that are more senior and ultimately become a consultant 'master practitioner'. The cycle would then continue with the consultant training young surgeons and handing on skills and knowledge.

The mark of a consultant surgeon is the ability to 'practice independently'. The real meaning of this phrase is not well defined and does not fit well with the likely organization of the surgical professions in the future where 'team working' is much more emphasized.⁶ One view of the organization of surgical teams involves groups of specialists in the generality of an area of surgery 'where team members work within a closely defined range of skills', rather like aircrew. Pilots cannot change between levels of competence or types of aircraft without demonstrating competence and usually after specific training.

The apprenticeship model, despite considerable criticism, served the UK well. The following are the principle advantages of this system:

- it is not time constrained, therefore the apprentice can learn at his or her own pace;
- training is close to the 'coal face', so that common conditions are seen and treated frequently;
- a close working relationship often develops between master and apprentice, helping with ongoing personal and professional development.

Critics of this system point to a number of weaknesses, including:

- the system fails to meet changing the needs of the profession;
- progress to more senior positions depends on availability of such a post and the degree of competition at that time;
- criteria against which to measure competency are generally lacking;
- poor trainer-trainee relationships could lead to underperformance.

Prior to the Calman Report, a typical career pathway in otolaryngology could be summarized as follows:

1. medical school (five to six years) to obtain medical degree. Provisional registration with the General Medical Council (GMC);
2. pre-registration house officer (one year), full registration with GMC;
3. senior house officer (approximately two to three years) including time spent in non-ENT posts such as general surgery, plastics, neurosurgery and accident and emergency. Obtain Primary FRCS (examination in anatomy, pathology and physiology);
4. registrar in otolaryngology (approximately three years). Entry into post by competitive interview. Obtain FRCS in otolaryngology during tenure;
5. senior registrar (approximately three years). Entry into post by competitive interview;
6. Maintain log book. Obtain Certificate of Completion of Higher Surgical Training;
7. consultant post. Competitive interview. Virtually permanent tenure.

Although the tenure of each post was fixed, the time in that grade was not. There was an imbalance in the numbers of posts available and a bottleneck between registrar and senior registrar grades. Over time, the UK system led to excessively long periods of 'training'. In some specialties, so few consultant posts were available that experienced and able trainees were stuck in the senior registrar grade for many years. This situation failed to satisfy the needs of the National Health Service or the trainees. European Working time legislation⁷ and the 'New deal on junior doctors' hours'⁸ have forced a rethink of UK training.

The Calman Report

In the early 1990s, Sir Kenneth Calman, as Chief Medical Officer, set up a working party that produced a report on the future direction of training.⁹ As part of the implementation of that report the grades of registrar and senior registrar were merged into the specialist registrar grade between 1995 and 1997. The new grade had protected training time and was not to be seen as part of service provision. Other features of the grade were to be a defined curriculum with clearer educational objectives and assessment. Protected training time has been widely implemented. Specialist registrars, however, remain important service providers. The bottleneck is now at the senior house officer (SHO) level. In ENT, the specialist registrar grade is tenable for six years; after this time, trainees 'fall off' the training scheme whether or not there is a post available or suitable for them. After four years of higher surgical training and satisfactory in-training assessments, trainees sit the Intercollegiate FRCS in Otolaryngology.

Current and future training in otolaryngology/head and neck surgery

At the time of writing, further changes to training are in the pipeline. The Chief Medical Officer, Sir Liam Donaldson, has published *Unfinished business*¹⁰ and *Modernising medical careers*.¹¹ The Working Time Directive continues to bite, reducing the hours available for training further.

In the current proposals, the senior house officer grade is to be abolished and the preregistration house officer time replaced by two post-graduate foundation years. The remaining period of specialty training will be confined to six years:

1. medical qualification;
2. two years' post-graduate training – foundation years;
3. specialist registrar – six years' specialty training based on new curriculum. Specialty-specific

MRCS after two years. FRCS (Otolaryngology) towards the end of the training period;

4. specialist in generality of ENT.

At present, there is no consensus as to the precise nature of what a specialist in this context will be or be able to do. 'Working in teams within a defined range of competencies' is the phase currently used. This is very different from 'independent practice'.

Terms such as 'emergency safe' have been widely adopted. Emergency safe in all aspects of ENT represents a high level of training. To deal with adult and paediatric airway problems, acute middle ear disease and orbital cellulitis and even severe nose bleeds requires a wide range of skills. There is no clarity about provision for super-specialized training in areas such as otology, paediatrics, skull base and head and neck surgery.

Curriculum development project

Under the auspices of the Surgical Royal Colleges, each specialty has been working on curriculum development. The new curriculum is much more explicit than any previous attempt and contains standards, criteria and assessment modalities. The ENT curriculum is near completion. The curriculum covers both generic and specialist skills. Using *Good surgical practice*⁴ as a guide, the following generic skills are specified and assessed:

- good clinical care;
- communication skills;
- maintaining good medical practice;
- maintaining trust;
- working with colleagues;
- teaching and training.

For example, communication skills have a specified objective and the appropriate knowledge, skills, attitudes and means of assessment are explicit.

Table 44.1 shows an example of the curriculum document relating to ENT communication skills. In the specialty-specific parts of the curriculum, a similar approach is applied and the knowledge, skills, professional attributes and assessment are specified. In addition, an indication of the depth of the ability or knowledge at each stage in training is given, where (1) is introductory level and (4) is advanced. Table 44.2 shows an example of the paediatric ENT curriculum document.¹²

CONTINUING PROFESSIONAL DEVELOPMENT AND THE MAINTENANCE OF SKILLS

All practitioners are obliged to keep up to date and monitor their performance. These obligations are laid out

Table 44.1 ENT communication skills. Objective: To communicate effectively with patients, relatives and colleagues in the different spheres of clinical practice.

Circumstance	Knowledge	Skills	Attitudes	Assessment
Within a consultation	Structuring the interview by identifying the concerns of patients and, where applicable, parents of paediatric patients	Active listening: Appropriate use of different question types. Use language appropriate for developmental stage of child. Check patients and where appropriate parents and child's understanding. Avoid jargon. Appropriate use of interpreters	Demonstrate empathy with patients and family. Be aware of importance of utilizing these skills. Be aware of importance of involving patients and parents in decisions. Offering choices. Respecting other views	Observed practice on ward rounds (teaching and business). Theatre practice and 'on-take'. Progress and outcomes recorded in trainer's report. Might include attendance at taught course
Breaking bad news	Structuring the interview and organizing setting. Normal process of bereavement and associated behaviours. Awareness of local policy on organ donation procedures and role of transplant coordinators	As above with emphasis on the avoidance of jargon. Encourage questions. Appropriate manner, avoiding undue optimism or pessimism	Demonstrate empathy sensitivity and honesty	Observed involvement in the clinical setting. Might include attendance at taught course. Information forwarded to trainer's report
With colleagues	How and when to communicate effectively with other members of the care team, including the use of handover rounds	To outline clinical case concisely. Identifying patients' and parents' concerns	Be aware of who requires information and expected level of detail. The contribution others can make to clinical decisions	Observed practice in clinical setting. Information forwarded to trainer's report
Complaints	Awareness of local policy for dealing with complaints	Deal with complaints in oral and written communication. Contribute where required to local complaints procedure	Demonstrate honesty and sensitivity in dealing with complaints	Observed practice and review of complaints with trainee as part of appraisal process

in detail in *Good medical practice* and *Good surgical practice*. The key points are:

- 'you must maintain the standard of your performance by keeping your knowledge and skills up-to-date throughout your working life';¹
- 'all surgeons must maintain their knowledge base and performance by fulfilling the continuing professional development (CPD) requirements of the Senate of Surgery and registering this with their college'.⁴

There are European and UK policy and frameworks for CPD.^{13, 14} The Senate of Surgery expects that all surgical

staff, other than those in training, will participate in CPD. This includes substantive and locum consultants, associate specialists and staff grades.

Requirements for continuing professional development

The minimum requirement for CPD in the UK is 50 credits per annum. One credit represents one hour of activity. CPD is viewed over a five-year cycle. Full- and part-time practitioners require full CPD (not *pro rata*).

Table 44.2 Management of common paediatric conditions.

Subject/topic	Knowledge	Clinical skills	Relevant professional skills	Assessment
Neck masses in infants and children	The embryology and anatomy of the neck with particular reference to the thyroid gland and branchial arch structures ⁴	Elicit clinical history and signs. Be able to deduce a differential diagnosis and formulate strategy to reach final diagnosis	Be able to advise the patient and parents of the treatment options ⁴	Knowledge-based assessment
	Understanding of the classification of neck masses ⁴	Able to examine the oral cavity, oropharynx and neck ⁴		Clinical assessment in out patients
	Awareness of the various hypotheses relating to the aetiology of neck masses ⁴	Be able to perform excision of thyroglossal and branchial cleft cysts competently ⁴	Discuss risks and potential benefits, potential complications and obtain informed consent ⁴	Supervised operating, including pre- and postoperative patient management
	Understand the principles of the medical and surgical management of neck masses and their complications ⁴	Recognize rarer causes of neck masses, such as first arch abnormalities, tumours, e.g. lymphomas, granulomatous conditions and lymphangiomas ³	Be aware of specific issues that relate to the management of children in hospital ⁴	Evidence of attendance on course dealing with issues relating to the surgical child

To understand the aetiology, presenting signs, symptoms and management of common paediatric ORL conditions. This module gives some indication of the breadth and depth of required knowledge and surgical skills. The list should not be considered to be fully inclusive or exhaustive.

A number of categories of CPD exist, the principle ones being internal and external. Practitioners need to participate in a mix of activities, such as outlined below:

- 25 external credits: for example, attendance at courses or conferences for which CPD credits have been awarded;
- 25 internal credits:
 - 10 hospital-based activities: for example, teaching rounds, pathology and radiology meetings;
 - 10 independent study: reading journals, writing papers;
 - 5 audit: contributing to and attendance at meetings.

At the time of writing, no CPD return has been checked, validated or audited. There is no policing of the system. The number of returns completed overall has been unsatisfactory, 63 percent in 2000. ENT surgeons have done better with returns of approximately 70 percent. Of the returns received by the Surgical Royal Colleges, little more than a half meet all the requirements.

Table 44.3 indicates the categories and amount of continuing medical education (CME) required by the Surgical Royal Colleges. **Table 44.4** summarizes the CPD returns held by the Royal College of Surgeons of England in ENT and surgeons in general.

Accreditation of continuing professional development points

The system for conferring CME credits is as follows. Applications are made to either the Surgical Royal College or specialist association. The application form requires basic details of the course or conference content. There is an obligation on the course organizer to keep an attendance register and to collect feedback from the participants. Credits are awarded, on behalf of the British Association of Otolaryngologists – Head and Neck Surgeons, by the Chair of the Education and Training Committee. Feedback from the course is then collected. Despite the current lack of supervision and enforcement,

Table 44.3 Annual continual professional development (CPD) requirements.

Division of CPD activity		Annual requirement
Internal CPD, hospital-based		
A	Postgraduate meetings	Minimum 10 CPD credits
B	Research meetings	
C	Journal clubs	
D	Other CPD	
Internal CPD		
E	Independent study	Minimum 10 CPD credits
Internal CPD		
F	Clinical audit	Minimum 5 CPD credits
External CPD, meetings and courses		
G	External meetings	Minimum 25 CPD credits
H	External courses	
I	Distance learning	
J	Postgraduate examinations work	
K	Visiting another unit	

Internal CPD (A–F) = 25 CPD credits, external CPD (G–K) = 25 CPD credits. Fifty credits per annum are in line with European and US norms. However, it is unclear why this number was chosen. In educational terms, the quality and appropriateness of CPD is considered more important than the quantity.

Table 44.4 Continuing professional development participation 2000–2001.

	2000	2001
No. surgeons registered for CPD		
All	5342.0	5888.0
ENT	579	573
Percentage of returns received		
All	63	60
ENT	71	72
Percentage of those returned who achieved (all)	46	46
Minimum CPD requirements for ENT	52	48

Note. As of February 2003, there are 719 ENT surgeons registered for CPD with the Senate of Surgery of Great Britain and Ireland, 80% of these are consultant ENT surgeons, 20% are non-consultant career-grade (NCCG) doctors.

all surgeons would be well advised to ensure that their CPD affairs are in order. These credits are reviewed at annual appraisals for National Health Service (NHS) consultants.

A review of applications for CPD credits to the British Association of Otolaryngologists over a six-month period is shown in **Table 44.5**.

Table 44.5 CME points awarded by BAO-HNS for applications received between October 2003 and April 2004.

	Points awarded
Number of events	32
Number of days	73
Number of points awarded	375
Average points per day	5.14

GUIDANCE FOR SURGEONS ON APPRAISAL AND REVALIDATION: SPECIALTY-SPECIFIC GUIDANCE FOR EAR, NOSE AND THROAT SURGEONS

The Joint Committee on Continuing Professional Development, chaired by Professor Graham T. Layer (reporting to Senate) is reviewing the system of CPD. New methods of registration and monitoring are likely. As part of this overhaul, specialty-specific guidelines are being drawn up. These specialty-specific guidelines should be read in conjunction with the parent generic document.

Good clinical care

DEFINITION

The ENT surgeon possesses a defined body of knowledge and skills within the area of the head and neck. These are used to collect and interpret data, make appropriate clinical decisions and carry out diagnostic and therapeutic procedures within the boundaries of their expertise. Their care is characterized by up-to-date, ethical clinical practice and effective communication with patients, other health workers and the community.

INDIVIDUAL STANDARDS

- Demonstrate diagnostic and therapeutic skills for ethical and effective patient care in the area of the head and neck.
- Access and apply relevant information to clinical practice.
- Demonstrate effective consultation services with respect to patient care and education.
- Establish therapeutic relationship with patients/families.

PRESENTING YOUR EVIDENCE

- Demonstrate awareness and application of good practice guidelines such as those produced by the British Association of Otorhinolaryngologists – Head and Neck Surgeons (BAO-HNS) (vestibular schwannoma, head and neck cancer documents

available on www.entuk.org) and others, e.g. *Good practice in cosmetic surgery*.

- Proof of involvement in audit, including national audit, if appropriate, e.g. National Sino-nasal Audit, National Prospective Tonsillectomy Audit.

Maintaining good surgical practice

DEFINITION

The ENT surgeon recognizes the need to constantly review activity and ensure that part of their regular CPD focusses on the generality of ENT, as well as on their own area of subspecialization.

INDIVIDUAL STANDARDS

- Attendance at annual general meeting of BAO-HNS (or equivalent body) at least every other year (home or abroad).
- Attendance at subspecialty professional surgical meeting at least every other year (home or abroad).
- Attendance at practical skills revision workshop, perhaps every five years.
- Involvement in regular audit meetings on a local/regional basis with involvement in national audit/attendance at national audit meeting every five years.
- If involved in teaching, attendance at 'Training the trainers' or equivalent course.
- Attendance at a critical appraisal course or equivalent.
- Regular review of a relevant journal, e.g. *Clinical Otolaryngology*, *Journal of Laryngology and Otology* or equivalent journal.

DEMONSTRATING YOUR EVIDENCE

- Certificates of attendance at courses.
- Copies of published articles, book chapters, etc.
- Guidelines written.
- Logbooks.

Teaching/training

DEFINITION

ENT surgeons have a responsibility for the training of students, trainees and other members of the healthcare team (including staff working in audiology, speech and language departments).

INDIVIDUAL STANDARDS

- Help others define learning needs and directions for development.
- Provide constructive feedback.

- Demonstrate an understanding of preferred learning methods in dealing with students and trainees.

DEMONSTRATING YOUR EVIDENCE

- Summary of formal teaching activities.
- Results of feedback from trainees on the effectiveness of teaching/training.

Relationship with patients

DEFINITION

Communication skills are essential for the functioning of an ENT surgeon and are necessary for obtaining information from, and conveying information to, patients and their families.

INDIVIDUAL STANDARDS

- Ability to establish and maintain rapport with patient characterized by understanding, trust, empathy and confidentiality.
- Ability to inform and counsel a patient in a sensitive and respectful manner, while fostering understanding, discussion and the patient's active participation in decisions about their care.

DEMONSTRATING YOUR EVIDENCE

- Evidence of involvement of patient groups when composing guidelines/information leaflets.
- Summary of complaints/letters of thanks.

Working with colleagues

DEFINITION

It is essential for an ENT surgeon to be able to collaborate effectively with a multidisciplinary team of expert health professionals for provision of optimal patient care.

INDIVIDUAL STANDARDS

- A collaborative approach includes the ability to recognize the limits of personal expertise, understand the roles and expertise of other individuals involved and explicitly integrate the opinions of those individuals into the management plan.
- Contributing effectively to other interdisciplinary activities implies the ability to recognize team members' areas of expertise, respect the opinions and roles of individual team members, contribute to healthy team development and conflict resolution, and contribute his/her own expertise to the team's task.

DEMONSTRATING YOUR EVIDENCE

- Evidence of involvement in multidisciplinary team meetings/clinics, e.g. head and neck oncology clinics, voice clinics, etc.
- Evidence of liaising with colleagues regarding emergency on-call cover, cover for absence, etc.

Probity, health and managerial

See generic continuing professional development document.

Future directions for training and revalidation

Surgery and its practice are evolving. The needs of society are changing and the pace of this change is accelerating. The modern surgeon has to respond to this situation. The demands on trainees and established surgeons will continue to grow. Resources will always be restricted. We will have to train the next generation of surgeons in considerably less time than at present. Ahead lies a simple choice between depth and breadth of training. Few will ever be able to acquire the full range of skills and experience of their predecessors. Those embarking on a surgical career will become 'specialists' in a shorter time. They are likely to have a proscribed range of skills and will from time to time need to demonstrate their on-going competency. Assessment of competence and demonstration of on-going performance requires considerable effort. One needs to determine precisely what is to be tested, devise ways to do so, ensure consistent assessment and determine appropriate standards.¹⁵

Revalidation of specialists and consultants may take many formats: bench top models, observation of practice, formal examinations or peer reviews. Whatever method is used, most surgeons will 'pass' the test. If they do not, then there is either something wrong with the test or the service will collapse. The General Medical Council is currently considering what form revalidation will take.¹⁶ In the future, a doctor will need to be registered, but will also need a licence to practise. The licence will be subject to revalidation. Revalidation will be possible by two routes, an appraisal route open to those working in a hospital or academic environment and an independent route in which the practitioner will have to demonstrate evidence of adopting the standards of *Good medical practice* and undertaking continuing medical and

professional development. Revalidation is due to commence in 2005.

Communication and the medical consultation

DAMIAN GARDNER-THORPE AND RICHARD CANTER

Introduction	559	Conclusions	566
The biomedical approach to patient care	559	Key points	566
The patient-centred approach	560	References	567
Core communication skills	564		

INTRODUCTION

Every day of our working lives we rely upon communication skills to build up relationships with our patients and colleagues. These core clinical skills are undeniably important in establishing trust and rapport with those who come to us for help and advice. To understand the increasing importance of communication skills, it is helpful to consider the way in which healthcare delivery has altered within western culture. The traditional biomedical approach to healthcare, which defines illness largely in terms of abnormal anatomy and physiology, has become outmoded because of its failure to recognize the full emotional cost of illness and the wider effects of disease upon the individual. The patient-centred approach to healthcare tackles the problem by focussing upon the patient's perspective.

There is, of course, an additional reason why the otolaryngologist takes a particular interest in communication issues. Whilst most of us are able to take our primary senses for granted, a proportion of our patients live with significant hearing loss or speech impairment, and this imparts upon us a special responsibility to remain sensitive to these differences without underestimating the ability of our patients to adapt to their unique environment. Just as our patients experience frustration in some clinical encounters, we too become aware of communication difficulties when our usual channels of conversation are blocked. To meet the challenge, we must acknowledge and accept our role in difficult encounters and devise strategies to meet them.¹

In this chapter, we discuss the traditional biomedical approach, its limitations in maintaining a balanced consultation and the concept of patient-centred care. We hope to explore aspects of the consultation, which

present particular challenges, and to understand the patient's perspective to generate a better awareness of our own behaviour in difficult clinical encounters.

THE BIOMEDICAL APPROACH TO PATIENT CARE

Over 50 years ago, Parsons examined the relationship between doctors and patients in order to describe their roles within society in the context of the prevailing attitudes towards healthcare.² Most patients accepted their responsibility to overcome illness as soon as possible, to seek professional advice from their doctor and to cooperate willingly with any advice offered. The doctor was expected to apply his or her knowledge and specialist skills to affect a cure. The doctor had a duty to act in the interests of the patient before his or her own and to adopt an emotionally detached and professional manner. In return for this, he or she was granted the right to enquire into intimate areas of personal life, to perform physical examinations and to assume a position of authority in relation to the patient. Whilst these values are still recognizable, the majority of patients now expect a very different style of healthcare and doctors have learnt to modify their traditional practice to meet an increased demand for a mutualistic approach to the consultation.

Intrigued by the changing face of healthcare, Byrne and Long³ tape-recorded over 2500 general practice consultations and analysed the behaviour of the doctors and the patients. They identified two extreme consultation styles, which they labelled 'patient-centred' and 'doctor-centred'. The patient-centred approach avoids an

authoritarian style and encourages the patient to take a pro-active part in the consultation. Key aspects of this include listening, moments of reflection, facilitation and the use of silence, but were found in no more than one quarter of the taped consultations. One characteristic of a doctor-centred relationship is the frequency with which the doctor will interrupt a patient's account of their illness. In a patient-centred encounter, the patient is encouraged to participate actively in the consultation whilst the doctor provides 'expert' knowledge, contextualizes appropriate management options and facilitates decision-making.

Other investigators have identified more sophisticated models of doctor-patient experiences. One such model describes four categories of interaction reflecting the balance of power that exists within a consultation. These categories are paternalism, consumerism, mutuality and default (**Figure 45.1**).⁴

Paternalism describes a traditional model of a passive patient and a dominant physician. This relationship is generally outmoded, but can offer significant support to frightened or anxious patients who derive comfort in such a traditional doctor-parent figure. Paternalism is especially important when patients are sick and vulnerable. It is of interest that when they are ill, physicians themselves prefer to hand over responsibility for their care to their colleagues and are most comfortable with a paternalistic model.⁵ However, they have usually chosen their attending physician with care.

A consumerist approach is one where the power relationship is reversed and the patient takes a more pro-active role in the consultation. The doctor adopts a passive role and accedes to the patient's requests, for example for a prescription, procedure or second opinion. Although the model at first sight espouses patient control, it may also reveal situations where the doctor is reliant upon the patient for goodwill or financial settlement. There are some groups in society, including the young, the better educated and those with previous experience of unhappy consultations, who are more likely to confront the doctor's traditional authority and expect a consumerist approach.

	Low physician control	High physician control
Low patient control	Default	Paternalism
High patient control	Consumerism	Mutuality

Figure 45.1 Consultation styles resulting from the level of interaction between the patient and the doctor. Redrawn from Ref. 4, with permission from Sage Publications.

A default situation occurs when neither doctor nor patient takes a lead in the consultation. This situation arises when the patient adopts an overly passive style and the doctor fails to assume control. This inevitably leads to a lack of direction and purpose in the encounter.

Mutuality exists when the physician brings their experience and expertise to the consultation, the patient brings his or her expectations, feelings and symptoms, and both parties participate in a joint venture to explore the possible outcomes and treatment options. Mutuality succeeds because of shared decision-making responsibility and because of a willingness of both parties to adhere to any agreed plan. The style has been described as a 'contractual' approach to patient care because within this arrangement the patient is free to seek care elsewhere when his or her expectations are not satisfied, and the doctor may withdraw from the relationship when patient requests are considered inappropriate, ethically untenable or impossible to meet.

Of course it is possible, indeed likely, that more than one model will be employed during a course of treatment. At the outset, when investigations need to be performed and the diagnosis made, a paternalistic model may be appropriate. This is particularly the case when patients are anxious, for example if there is the possibility of cancer. Later, when treatment options are discussed, a model of consumerism or mutuality would be more appropriate. There is a case for negotiating these different models of consultation style with the patient. The physician may therefore suggest that to begin with he or she 'takes over the running of the care', but later when treatment options are to be discussed, he or she will switch to a more mutualistic consultation style.

THE PATIENT-CENTRED APPROACH

There are several aspects of the consultation which we might wish to consider in the context of the evolution of the patient-centred approach. These include issues of power, an understanding of basic ethical principles and the factors which determine compliance. A basic understanding of these may help to understand why communication sometimes fails.

Issues of power

Doctors, perhaps subconsciously, control the behaviour of their patients. Sometimes the reverse is also true. The balance of 'power' depends upon several patient factors including the extent of the patient's medical knowledge and their capacity to choose between options. Nevertheless, an appreciation of power dynamics helps avoid the risk of applying unintentional or unjustified influence on our patients.

To understand the role of power in the clinical encounter, let us define power as the means by which A gets B to do something, where A might be the doctor and B might be the patient.

Power is exerted upon patients in several ways. The most obvious form is expert power, in which a doctor exerts influence by virtue of his or her possession of specialist knowledge. Expert power is rarely used alone, but is instead exercised in conjunction with other forms of power including power of legitimacy (power devolved to a doctor from the Royal Colleges or the General Medical Council), coercive power, charismatic power and of course the offer of rewards, including relief of symptoms.⁶ Most clinicians exercise these elements of power to suit their consultation style and to achieve a degree of patient compliance. Nevertheless, this is a simple model of power and it is not that helpful in understanding power in the clinical encounter.

Lukes⁷ produced a generalized model of power that does shed light on the clinical situation. He saw power as operating in three dimensions: first dimensional power is when A forces B to do something, the second is that in which A controls the agenda in any interaction with B and the third dimension, in which A controls the world view of B.

So how does this power model apply to the clinical encounter?

First dimensional power is analogous to coercive power. It might be exercised appropriately in emergency situations, in certain acute psychiatric states or when patients are extremely distressed or anxious and do not wish to debate alternative choices. First dimensional power is frequently exercised in the emergency arena, for example, when a stridulous patient is told that he needs a tracheostomy or a patient with a brisk epistaxis is told that he must undergo immediate nasal packing, even if the treatment itself causes agitation or distress.

Second dimensional power is exercised when the doctor deliberately steers conversation towards or away from certain topics in order to influence final outcome. Patient choice will be biased because of a selective presentation of information. This may happen when consultation time is limited or when doctors make it difficult for patients to ask questions in clinic. Second dimensional power may also result from the increasing reliance upon guidelines and protocols which dictate outcome goals without offering any flexibility for alternative options within the process of the consultation. It also includes the power to silence or make it difficult for the patient to ask certain questions.

Third dimensional power is harder to appreciate. It manifests itself when a doctor constructs for his or her patient a world view of disease and treatment. The patient believes he or she moves autonomously, but is in fact under the influence of the flow of medical knowledge as presented by the doctor. Consider for a moment the situation faced by a patient with malignant disease of the

larynx, who has to make choices about the treatment options of palliation, radiotherapy, chemotherapy, surgery or various combinations of each. The encounter is framed within a definition of malignant disease in a conventional biomedical model. A discussion follows, looking at the effectiveness of each of these treatment options, based upon the physician's understanding of results reported in the medical literature together with his or her experience of previous cases. The patient is apparently free to choose, but these choices have been shaped and polished by the manner in which they have been presented.

The biomedical world view can be demonstrated quite easily, because within a conventional biomedical framework model there would be no place for herbal medicine, acupuncture, osteopathy or any other of the many complementary medical alternatives. Indeed, when these issues are raised within a conventional medical consultation, they are frequently problematic.

An ethical framework

An ethical framework is required to place the patient's interests at the centre of the decision-making process. Because of the imbalances that exist between doctors and patients, not only in terms of power but also in terms of knowledge and skills, there is a very real benefit in having a set of principles, sanctioned by society, to guide the doctor in making the best decisions with or on behalf of his or her patients. Such ethical principles have existed since Hippocratic times and have evolved through history in response to novel treatments, new dilemmas and changing attitudes within society.

The most widely employed ethical framework is the four principle framework, or *Principlism*. It comprises a simple, logical and culturally sensitive approach to ethical problems and is useful for most clinical situations where there is a difficult conflict of interest. The four components are autonomy, justice, beneficence and nonmaleficence.⁸

The first of these, autonomy, is the capacity to think and to have freedom to act upon these free thoughts without let or hindrance. Autonomy empowers patients to make decisions for themselves. Full self-determination is not possible within the constraints of a civilized society as we cannot each expect to live according to our own personal rules. Instead we must act within the rules of society and exercise our right to autonomy within cultural boundaries and the laws of the land. In the context of the medical consultation, the individual's right to autonomy should be respected as long as it does not adversely affect other members of the community. This means that the patient has the absolute right, in almost all situations, to choose their preferred treatment and be free to reject any intervention without prejudice. There are, of course, situations where the patient delegates his or her autonomy to the doctor – 'You decide for me,

doctor' – in which case the doctor must defer to the basic Hippocratic principles of beneficence (doing what is good) and nonmaleficence (not doing that which is harmful).

Situations exist where the doctor bypasses the principle of autonomy. Usually this results from the patient's lack of capacity to exercise autonomy resulting from immaturity, disability or disease, but it also happens when the individual's actions impinge upon the well-being of others and in this instance the doctor must consider the rules of justice. Nevertheless, it follows that we need to be honest and open with our patients, consult them before we do things to them, keep patient information confidentially and respect a patient's right to choose what is and what is not done to them whenever possible.

Beneficence and nonmaleficence are the oldest two principles. Beneficence is the duty to do that which is best for the patient – even if this is at some personal cost to the doctor. Beneficent traits include basic qualities of a doctor including friendliness, good manners and good time-keeping. Nonmaleficence is the duty to do no harm. However, it is all too easy to envisage a situation where an intervention has the potential to improve an outcome, but only with the risk of serious side effects. We are responsible for considering the best option for our patients, 'all things considered'.

We run into difficulties, especially in the modern technological world of medicine, when we cause harm to our patients through an intention to do well. Although the principle of nonmaleficence tempers us in our decision-making process, we must try to avoid the tendency towards inappropriate paternalism in deciding the best management option for our patients – to do so takes choice away from patients and risks a breach in the duty of autonomy. Consider this in the context of another, perhaps more traditional approach where arrogance is held as a virtue, preferable indeed to the virtue of humility: 'if you agree that the physician's primary function is to make the patient feel better, a certain amount of authoritarianism, paternalism and domination are the essence of the physician's effectiveness'.⁹

Justice, or a 'just' distribution of health care resource focusses upon making fair decisions when there are competing claims. Justice is particularly important in rationed health care systems where available services are shared out among many individuals. Doctors are sometimes responsible for deciding how to share out these resources, which include their time and skills, as well as expensive investigations and treatments, and this may not necessarily mean being even-handed to every patient.

Compliance

Compliance has been defined as the 'extent to which the patient's behaviour coincides with medical or other health care advice' and applies equally to lifestyle advice,

accepting prescription medication and following advice to undergo surgery.¹⁰ Amongst doctors, there is perhaps a naive expectation that patients should comply with their advice, though in practice it is hard to determine the reasons why patients do not act upon guidance.

Not surprisingly, there is increasing interest in the factors which underpin compliance. The three prime factors are believed to be a good understanding of advice, a high level of satisfaction and an ability to recall information handed over by the clinician.

While it is clear that compliance depends upon a good level of understanding between doctor and patient, there is a tendency for health care providers to overestimate the patient's medical knowledge. When a group of patients were asked to describe the approximate position of vital organs within the body, fewer than one-fifth were able to locate the stomach and fewer than half knew where to find the heart or liver.^{11, 12}

Medical jargon is often confusing and despite our best intentions we frequently lapse into a technical vocabulary which patients cannot comprehend. The word vertigo means very different things to different individuals and the ear, nose and throat (ENT) specialist will also be aware of the imprecise usage of this term throughout the profession. We need to be sure that patients understand our definition of terms and that we appreciate their use of descriptive language too. One straightforward way to check the level of this understanding is to ask patients to repeat back in simple terms their interpretation of the situation.

Some expressions run the risk of trivializing the serious nature of a medical problem, for example 'just pop on the couch' or 'we'll just have a quick look at your ear'. Nevertheless, we need to remain sensitive to the patient's level of understanding and contextualize our language according to patients' individual needs. There are circumstances where rapport is strengthened by setting out a clear agenda at the start of a consultation, by explaining, for example that we may interrupt in order to focus on to particular aspects of a history. An example of this might be during a consultation for 'dizziness' where a fastidious approach to history taking is required to reach a reliable differential diagnosis.

The capacity for information recall varies greatly between individuals. The factors which influence recall include the volume and complexity of the message, as well as the impact that it has upon the individual. Evidence from primary care suggests that surprisingly little factual information is retained by the patient following the end of the consultation. For example, in one study over a third of patients failed to recall the name of their prescription medicine and a quarter failed to appreciate the duration of the course of their medication.¹³ Given the particular importance of accurate information transfer in surgical specialties, one approach to reinforce handover of knowledge is to dictate the clinic letter in the presence of the patient, in plain and unambiguous English, and to offer the patient a copy for his or her own records.

A number of interesting cognitive factors explain how patients behave in particular health settings. Heuristics are 'rules of thumb' which explain patterns of behaviour, for example in relation to perception of risk or threat from disease. Weinstein¹⁴ coined the term 'unrealistic optimism' to account for the observation that individuals tend to underestimate the risk of a threat to which they are specifically vulnerable. He tested the popular belief that people think themselves invulnerable, by demonstrating in a group of college students a systemic error in estimating personal risk from negative and positive threats. For example, the students overestimated their chances of enjoying their first job or owning their own home, but underestimated their risk of contracting a venereal disease, having a drink problem or getting lung cancer. Their misguided perceptions result from a complex interplay of factors including differing egocentric biases, personal experiences and stereotyped beliefs. Other heuristics influence susceptibility judgements; for example, the tendency for individuals to overestimate their personal risk from less likely causes of death, but to underestimate the risk from more common ones.¹⁵ An appreciation of risk perception is especially pertinent to those taking informed consent for surgery.

Simple and effective techniques for increasing compliance include provision of written information, keeping explanations simple, repeating important points and the judicious use of follow-up appointments. We should remember too that patients tend to recall the first and last pieces of information that they receive – the primacy and recency effects.^{12, 16}

Consultation models

In accepting the validity of the patient-centred approach, we can consider basic consultation theories which help explain the decision-making process from the patient's perspective. A number of these models overlap the field of health psychology and explore the role of the patient's motivation, health beliefs and the factors which underpin compliance.

Within the traditional paternalistic encounter, the consultation essentially involves the transfer of knowledge from expert to lay person. Whilst there may be many straightforward medical complaints where psychological and emotional components are less important, it is increasingly recognized that patient compliance and

satisfaction improve when the doctor contextualizes the disease within a more holistic approach.

Byrne and Long³ outlined the essence of the doctor-centred relationship, largely analogous to the 'paternalistic' approach (**Figure 45.2**).

Pendleton *et al.*¹⁷ devised a patient-centred model which encourages the doctor to explore the patient's ideas, concerns and expectations and to frame the consultation in a problem-solving approach. One vital tenet of Pendleton's model is the maintenance of a healthy doctor–patient relationship:

- define the reasons for the patient's attendance;
- consider other problems (including risk factors for current complaint);
- negotiate the correct course of management of each of the presenting problems;
- achieve a shared understanding of the problem – both doctor and patient;
- involve the patient in management and encourage patient responsibility for care;
- use resources and time efficiently;
- establish and maintain a healthy doctor–patient relationship.

Neighbour,¹⁸ in perhaps the most widely used patient-centred model, espouses an appreciation of subtle clues in the consultation, verbal and nonverbal. The model establishes good doctor–patient rapport and helps the clinician identify and address underlying concerns. This elegant model uniquely recognizes the importance of the role of the doctor and reminds the clinician of his personal risk of stress, anxiety and burn-out:

- **connecting:** where the doctor establishes rapport;
- **summarizing:** clarification of the patient's reason for attendance;
- **handing over:** joint negotiation of the correct course of management;
- **safety netting:** managing uncertainty and planning for the unexpected;
- **housekeeping:** staying in touch with emotions and awareness of burn-out.

While none of these consultation models provides a comprehensive or universally reliable guide to a successful outcome, each has its place in dealing with difficult clinical encounters. Through the evolution of consultation modelling there has been a gradual shift towards a patient-centred emphasis which is likely to be

Figure 45.2 The traditional doctor-centred model. Redrawn from Ref. 3, with permission from HMSO.

the trend, at least for the current generation of healthcare providers.

CORE COMMUNICATION SKILLS

In an encounter between two individuals, it is said that less than 35 percent of the contact is established through verbal means, whilst 65 percent or more is conveyed through nonverbal cues including facial expression and eye contact.¹⁹ Patients are particularly sensitive to nonverbal cues from their doctors, but doctors are often unaware of their influence in this respect. It is important to recognize the importance of subtle behavioural cues which are highly influential in determining the direction of the consultation and the subsequent outcome.

It is obvious that our patients are likely to prefer a more relaxed consulting environment. Since nonverbal methods of communication include the use of eye contact and body language, we may consider how these are influential in the consulting room. These factors include the layout of furniture, the relative positions of doctor and patient and the distance between them. A relaxed interaction is more likely when chairs are positioned at the same height to ensure good eye contact. A desk represents a potential barrier between the doctor and patient and may be an important factor in limiting the free flow of conversation. In one interesting experiment, the influence of the desk was analysed during consultations between a cardiologist and his patients. On alternate days the cardiologist removed the desk from his consulting room to assess the impact upon nonverbal cues and body language. When the desk was absent, more than half of all patients sat back and relaxed, but when the doctor was positioned behind the desk fewer than one in ten assumed a relaxed body posture and this corresponded with a drop in the level of meaningful interaction between the two.¹⁹

Knapp²⁰ looked into the importance of seating configurations in more detail, not only in the context of the medical encounter but also for its significance in business meetings and any other number of social occasions. He identified four independent seating positions for any interaction: the corner position, the cooperative position, the competitive-defensive position and the independent position (Figure 45.3).

In the corner position, two individuals are positioned in such a way that the corner of the desk intervenes. It usually results in casual friendly conversation. It allows unlimited eye contact and a full appreciation of gesture. The corner of the desk behaves as a partial barrier but does not intrude as a territorial division. The cooperative position differs from the corner position by the absence of any barrier and a straight face-to-face seating posture. Whilst this favours a mutualistic relationship, a number of individuals feel threatened by the lack of a firm boundary.

Figure 45.3 Examples of seat and desk arrangements. (a) The corner position; (b) The cooperative position; (c) The competitive-defensive position (the territorial line); (d) The independent position. Redrawn from Ref. 20, with permission.

In the competitive-defensive position, the desk constitutes a firm physical barrier. Not only does this prevent intimacy, but it may create competition for control of the consultation. An imaginary territorial line is evident between the doctor and patient. In contradistinction, the independent position is adopted by those who want to avoid interaction, just as people do when they sit in a library or on a train. This style would clearly be alien to a sensitive medical encounter and cannot be recommended!

Listening is of course a core communication skill in clinical medicine, though little attention is paid to its full importance. Burnard²¹ describes three levels of listening. The first is at the linguistic level, comprising an understanding of words, phrases and metaphors. The second level is paralinguistic, where the listener takes cues from timing, volume, pitch and accent including the use of ‘umms’ and ‘ahhs’ in the fluency of speech. The third level is an appreciation of facial expression, gesture, touch, body position, proximity of doctor and patient, body movement and eye contact.

The first level involves the content of speech without any emotional connection. Second level skills allow the doctor to develop a 'free floating' attention, observing patient cues other than words alone. At the third level, the doctor maintains a 'free floating' attention whilst noticing paralinguistic features and nonverbal cues, as well as noting his own internal thoughts, sensations and feelings. Watkins²² describes this as 'resonance' between doctor and patient, whereby information determined from the history is weighted according to nonverbal cues and is characterized in such a way that any underlying anxieties are exposed and addressed.

Eye contact serves many functions, and used appropriately, establishes trust, demonstrates integrity, controls the level of intimacy and assists in information transfer. The comfortable level of eye contact depends on the context of the consultation, the physical distance between the participants and their degree of familiarity. An appropriate distance between the doctor and patient is hard to gauge, but it has been established that as distance is reduced, many start to feel uncomfortable, and a distance of less than 30 cm produces tension in most individuals.²³

Frustrating encounters

Notwithstanding our best attempts to construct the ideal consultation, each and every doctor encounters patients from time to time who provoke an inner sense of frustration or irritation, and this may be for no discernable reason. These patients have been identified within the general practice setting as 'heart-sink' patients. While general practitioners are more likely to see their patients repeatedly, the same emotional response to patients is encountered by doctors within hospital practice, especially when patients return with new symptoms on repeated occasions or when they fail to respond to treatment. One interesting aspect of this problem is that a heart-sink patient to one is not necessarily a heart-sink to another. This is explained by understanding that frustration is produced by both doctor- and patient-related factors, and probably represents a generalized failure of the doctor-patient interaction at a fundamental level. Of the many factors involved in a heart-sink encounter, doctor factors not surprisingly include low job satisfaction, the perception of an excessive workload and a lack of training or experience in counselling or communication skills.²⁴

The heart-sink may be avoided by improved communication strategies, including a commitment to the ongoing development of consultation skills and identification of situations which cause stress. A number of special skills exist to combat the heart-sink encounter including a 'holding strategy' for listening and understanding the patient's problems without feeling the need to tackle all issues in one sitting.

Breaking bad news to patients

Sharing bad news with our patients is a difficult task to do well, so it is a little surprising that so often this has been the responsibility of relatively inexperienced members of a surgical team. A number of simple techniques may help to undertake this more sensitively. Some appear obvious, such as planning the consultation in advance, checking the facts and avoiding interruptions to ensure privacy. Breaking bad news can take a significant amount of time and it is important to avoid being rushed. We need to use simple straightforward language and avoid jargon. Many patients value the invitation to bring a relative or close friend for support, though we should be clear in establishing the nature of the relationship in order to understand how the news will impact upon them as well.

Nonverbal messages are as important as verbal ones. Patients need to be given sufficient time for silence, tears or anger. Even when the future looks bleak, be careful in using the phrase 'nothing can be done' since there are always ways of encouraging hope in any dire situation. Nevertheless, it is equally important to admit when we do not know the answers to difficult questions, such as life expectancy after a diagnosis of terminal disease. Most patients value the offer of ongoing support and follow up is especially valuable.

Dealing with loss

Surgical patients inevitably experience concerns about the potential disfigurement and loss of function which result from our actions. We have a clear duty to address these issues in appropriate depth. Within our specialty, patients undergo radical neck surgery, lose the functions of speech, swallowing, balance and the ability to hear properly. Perhaps not surprisingly, those who cope less well with loss of body function are those with a history of premorbid anxiety or depression, and these are factors that are easy to overlook in a busy consultation.²⁵ Consequently, a professional assessment of mental health may be a helpful part of preoperative planning for some of these patients prior to major surgery.

The reaction to a loss of function depends upon many complex factors. A sudden unexpected loss may magnify shock and increase difficulty in coping, and our colleagues in primary care will testify to the longer-term consequences of mental health problems after serious disease. Doctors are advised to be honest and frank to their patients in the early stages of disease, especially when there is little hope for recovery.

There are circumstances in which patients are disenfranchised from their normal pattern of grief and these include elements described as hidden and concealed losses. Hidden loss takes place when patients are unable to share their experiences with even close friends or relatives, perhaps because of the shame of human

immunodeficiency virus (HIV) or because of religious or social stigma. Concealed loss happens when relatives or doctors fail to share information with patients because of a misplaced belief, often with good intentions, that the patient cannot cope with bad news. This rationale for concealment is usually poorly grounded and an opportunity to come to terms with reality may be missed. Many patients have a remarkable capacity to adapt to bad news and may become angry if they later learn that information has been withheld.²⁶

Whether consciously or unconsciously, avoiding grief can lead to difficult outcomes both for doctors and for patients. While doctors are conditioned to remain calm in adversity, they often experience difficulty describing their emotions once a stressful situation has passed. Those who learn to express their emotions report greater satisfaction at work and presumably function better as doctors.²⁶

Loss of hearing

The limitations caused by hearing loss depend greatly on the age of onset and on the extent of any residual function. Prelingual deafness is that in which impairment of hearing predates language acquisition and by definition necessitates development of communication skills by alternative means. It is misleading to consider prelingual deafness a loss of function without considering the rich alternative language skills that arise through the use of sign language. The visual-spatial axis of sign language may be developed in the first few years of life, during the critical period of language assimilation, to the same extent as the more common linguistic route. The distinction between truly deaf individuals and those who become deafened later in life is important. Properly nurtured, the congenitally deaf individual is able to develop normal communication skills within the deaf community without any requirement for the spoken word, whereas the individual who encounters hearing loss after normal development suffers an immeasurable handicap without augmentation or alternative aids.

THE DEAF COMMUNITY

Absence of hearing does not necessarily correspond to handicap. Deaf communities thrive throughout the world, enjoying their unique cultural existence with a vibrant and expressive language. Different forms of sign have developed across the world independent of spoken language.

In 2003, the UK Government formally recognized British sign language (BSL) as a language in its own right, banishing the fallacy that it represents a rudimentary translation of spoken English. The ruling affords BSL the status of a native British language, equal to Welsh or Scots Gaelic as a minority language. As many as 70,000 people in the UK communicate in BSL, a rich and complex

language employing hand shapes, facial expressions and body language within defined spatial boundaries.

To understand the importance of this landmark recognition, one must recall the bigotry and persecution experienced by generations of deaf individuals, many of whom were forced to learn to vocalize language and suppress their natural tendency to sign during the critical time of language acquisition.

Our role as health care providers is to encourage and respect the autonomy of the deaf community and to assist with technological innovation or general professional services, when required.

ACQUIRED HEARING LOSS

In routine practice we frequently encounter patients with acquired hearing loss. There are a number of simple methods for improving communication within the consultation. Slow, deliberate speech of adequate volume in a room with low ambient noise will assist those with a modest hearing loss. A face-to-face position and clear enunciation of words enables lip reading in those with longstanding loss. Other simple but underused communication aids include diagrams, models and picture boards.

CONCLUSIONS

There has been a cultural shift in the way in which doctors and patients interact and this has resulted in the evolution of the patient-centred approach to health care. Despite this, there are many elements of the consultation which are difficult to recognize, including issues of empowerment. Since our prime responsibility is to act in our patients' best interests, it is important for us to understand the ways in which we influence our patients, whether consciously or not. We also need to recognize our own feelings and anxieties when we deal with difficult situations and to appreciate the particular difficulties which arise when we deal with patients with sensory deficit. To learn good communication techniques takes time and experience and inviting feedback from patients should be encouraged rather than feared. It is a useful idea to encourage feedback from patients either during or at the end of the consultation. As the old saying goes 'asking saves a lot of guesswork'.

KEY POINTS

- The traditional approach to the consultation is being superseded by a more patient-centred ethos.
- Power dynamics play an important but often unappreciated role in the doctor-patient encounter.

- The four-principle framework is comprised of beneficence, nonmaleficence, autonomy and justice.
- Compliance is related to the level of patient understanding, patient satisfaction and recall.
- Consultation models offer a technique for understanding the doctor–patient encounter.
- Listening to patients is an underused clinical skill.
- Most doctors experience heart-sink situations at some point – it is important to recognize the signs.
- Remember the grief reaction: denial, anger, despair and acceptance.
- Simple techniques, such as models and diagrams, are highly effective methods of communication.

INTRODUCTION

John Shaw is a 45-year-old ear, nose and throat (ENT) consultant and has spent the last eight years working in the ENT unit of a large London hospital. During that time, he has rarely questioned the way that he communicates with his National Health Service (NHS) patients or reflected on his attitude towards the other health care professionals who work with him. John's behaviour at directorate meetings is proof positive that at least one of the consultants' unwritten rules has survived the new millennium: 'Turn up, do the work, don't get noticed!' After all, if John maintains his distance, does the job he's always done and doesn't stick his head above the parapet, he will avoid getting sucked into management issues.

The multidisciplinary team (MDT) that John says he's part of is 'multidisciplinary' and a 'team' in name only. In reality, team members are neither accountable to each other for their clinical practice nor do they work together in a multidisciplinary way. They are a group of individuals who share the occasional clinical meeting. The consultants themselves work in silos, in separate clinics, rarely coming together to coordinate patient care – although they often treat the same patients. If you asked John, he would not know whether his practice varied from Sarah's across the corridor or whether he was making different decisions about treatment of the same patient.

Recently, John had a 'near miss' when he divided a facial nerve trunk during a parotidectomy. Even though he had resutured the injury at the time, he felt that it was better that he kept this complication to himself. He knew from past experience that if he reported it, he would be blamed. Similarly, he did not want his mistakes exposed to colleagues through his department's new system of multidisciplinary audit. After all, it may draw attention to deficiencies in his surgical experience and patient selection for surgery, and he would in all probability be held responsible. What's more, audit threatened to interfere with his clinical work and generally took up too much of his time.

Things had been like this in ENT as long as John could remember. The service was under pressure from all sides: long waiting lists, lack of funding, insufficient resources, including incompatible information technology systems and too few consultants to provide the modern service expected. As far as John Shaw is concerned, he does the best that he can for his patients under the circumstances. He does not hear nor want to hear of any complaints, so he assumes that his patients must be satisfied with their treatment and care. Mind you, he has never asked them.

John feels that people and the system always want more from him, always want changes to the historic order of things. He has become more sceptical about anything labelled modernization or innovation, because he has seen it all before: too many initiatives come and go in the NHS.

A few years ago John's hospital was involved in a clinical governance review. The Commission for Health Improvement (CHI) undertook reviews of clinical governance arrangements in NHS organizations throughout England and Wales until April 2004, when it was replaced by the Commission for Healthcare Audit and Inspection (Healthcare Commission (HC)) (www.healthcarecommission.org.uk).

Clinical governance is one initiative that has not come and gone. The clinical director continues to emphasize it within the department. What exactly is clinical governance to people like him working hands on with patients? The definition he has seen says that it is:

A framework through which NHS organisations are accountable for continually improving the quality of their services and safeguarding high standards of care by creating an environment in which excellence in clinical care will flourish.¹

But, what does that mean for the way that he works in the unit?

WHAT IS CLINICAL GOVERNANCE?

'People can't grasp that clinical governance is an integral part of your job – it's just what you're doing.' These words from a clinician show an awareness that clinical governance is a unifying concept; it brings together the aspects of

care implicit in the work of any health professional or support worker who day-in, day-out strives to ensure that the service they offer patients is safe, and of the highest quality that they are able to provide.

Clinical governance is not just about risk management. In an organization where it is fully integrated, there are not only effective processes for identifying and managing risk; there are clear lines of accountability; there is alignment of processes with systems and behaviours (Figure 46.1). In the clinical governance organization:

- patients come first;
- care is delivered with the highest standards of patient safety;
- clinicians work collaboratively, in multidisciplinary teams;
- there are clear lines of communication between staff;
- staff, regardless of their position, feel valued, included, listened to and empowered;
- there is regular clinical audit of services;
- clinical decisions are supported by research evidence;
- patients' complaints and clinical errors are reviewed and acted upon;
- there are professional development opportunities through education and training;
- staff have access to current information technology systems;
- data and information are used effectively to review service quality and support decisions and processes;
- the organizational culture is open, questioning and blame-free;

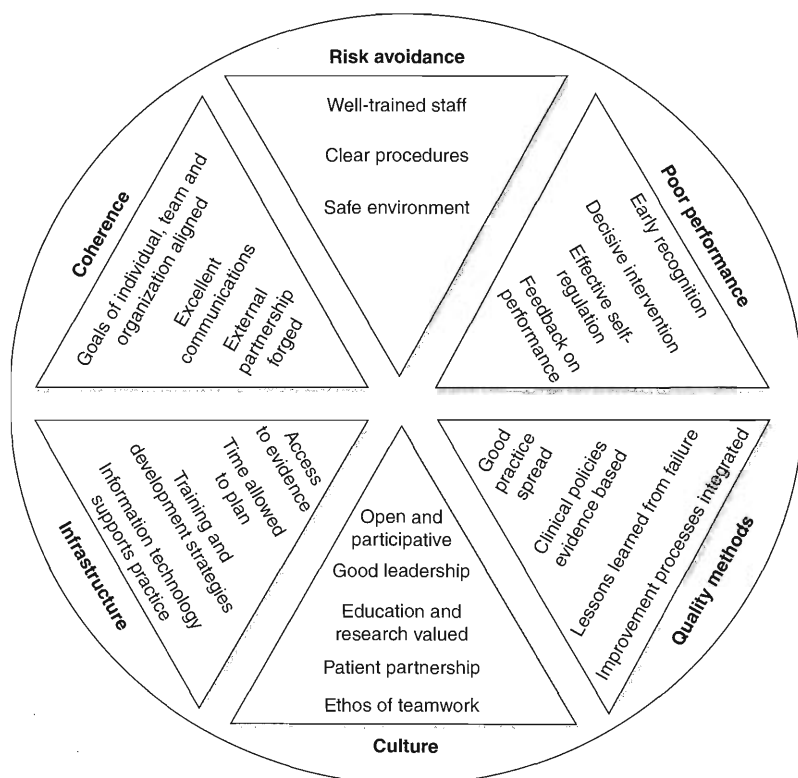

Figure 46.1 Integrating approaches of clinical governance. Redrawn with permission from Ref. 1.

- clinical governance is high on the corporate agenda;
- there is strong leadership throughout the organization.

An organization where clinical governance is mainstream would be able to provide support for clinicians like John Shaw where it is needed. This would enable them to be more accountable for the care they deliver, to re-examine their ways of working and to reflect on whether changes in their attitude and behaviour would not only benefit their relationships with colleagues, but place patient rather than professional concerns at the centre of their thinking.

However, developing an organizational culture, where staff feel they can freely report and learn from their mistakes, does not happen overnight. NHS trust chief executives and clinical governance leads have identified cultural difficulties as a major barrier impeding the successful implementation of clinical governance and there is much scope for improvement in communications between trust boards and clinical teams.² For clinical governance to be fully integrated throughout local NHS organizations, such barriers need to be overcome, but this is not easy if individuals are defensive about their clinical performance and continue to relate to others in ways that maintain hierarchies between professional groups.³

Hackett *et al.*⁴ have identified three features of organizational life which need to be tackled by chief executives if a successful clinical governance framework is to be established: culture, leadership of changes to introduce the systems and dealing with established networks of power. They also state that any effort to implement clinical governance must ensure that consultant medical staff, as the key organizational stakeholders, are carried with the change, since the chances of success are limited if they are not ‘signed up’ to the process, its aims and values. (This point also applies to the NHS programme for information technology, *Connecting for*

Health. It has been widely reported that the programme has had difficulty in winning over the very clinicians who will apply new IT systems in the future, because they have not been fully engaged from the outset of the programme.)⁵ The values of clinicians and their managers may well differ and without constructive dialogue, this may affect doctors’ attitudes towards clinical governance arrangements in their hospitals (see **Table 46.1**):

The clinician’s traditional values...professional autonomy, the focus on individual patients, the desire for self-regulation, and the role of evidence-based practice...Those of managers: the emphasis on populations, the need for public accountability, the preoccupation with systems and the allocation of resources...we should not pretend there are no differences between the way that doctors and managers see the world.⁶

The goal however, whether doctor or manager, should be a common one: continuous improvement in the quality and safety of care for patients and for those who use health services.

The required change in organizational culture to make clinical governance mainstream is movement towards a ‘learning organization’.⁷ This means that NHS organizations learn from their mistakes, including adverse incidents and near misses;⁸ that the results of clinical audit are widely shared and acted upon; that evidence-based practice is encouraged and that staff themselves are encouraged to learn and develop their skills as healthcare professionals.

WHY CLINICAL GOVERNANCE?

Clinical governance sits within a national quality framework which drives, supports and reinforces the

Table 46.1 Clinical governance: barriers to implementation in trusts.

Behavioural	Cultural
Reluctance of professions to change ‘yet again’	Concern that clinical time will be invested in clinical governance (CG) systems at the expense of patient care
‘Why bother’ syndrome – created by lack of suitable evidence-based guidelines combined with lack of time locally	Belief that systems based on evidence, guidelines and protocols may discourage clinical judgement and freedom for individual cases
Resistance to CG systems as another vehicle for managerialism of professions	CG as a management agenda to improve performance by reducing or controlling costs
Absence of good clinical leadership in some specialities locally and resources to invest in a satisfactory output	Perceived tension between the mechanisms for self-regulation by doctors and the management culture of accountability, hierarchy and control
Erosion of powerbases: Threat to power, prestige and status of internal stakeholders in organization	Reticence to share CG systems outputs with the public as this will undermine professions, clinical services and individual doctors
	Incident reporting undermined by increase in litigation and the culture of medicine which emphasizes professional autonomy, collegiality and self-regulation

Adapted from Ref. 4.

introduction and implementation of local NHS clinical governance activities. Before explaining what systems have been established to improve standards of treatment and care, and monitor and inspect the quality of services provided, it is necessary to establish why it was felt necessary to introduce clinical governance in the NHS – a public service where for years the notion of ‘quality’ was implicit. The recruitment of well-trained staff, good facilities and equipment were considered synonymous with high standards of patient care (see Table 46.2). *The NHS Plan*²⁰ and *Delivering the NHS Plan*²¹ further emphasized the importance of successful implementation of quality structures and mechanisms to help reinforce the NHS quality strategy. A range of national structures and mechanisms was established to develop national standards, provide effective monitoring and inspection of progress and ensure local delivery of this national policy for high quality health care. Clinical governance is central to the delivery of this strategy and provides the framework by which local organizations work to improve and assure the quality and safety of clinical services for patients.¹⁸

SETTING STANDARDS FOR DELIVERY ON QUALITY

Standards are the cornerstone of quality assurance. The National Service Frameworks (NSF), the National Institute for Health and Clinical Excellence (NICE) and

healthcare standards are instrumental in establishing and maintaining them across the NHS. One of the key aims of the Health Care Standards Unit (HCSU) is to develop standards for better health (SfBH).^{22, 23} These 24 core standards and the optional developmental standards, describe the level of quality that health care organizations, including foundation trusts, and private and voluntary providers, are expected to meet. All NHS organizations in England are required to take them into account when developing, providing and commissioning healthcare.

They are grouped into seven domains including safety, governance, patient focus and accessible and responsive care. The standards are grounded in clinical governance as is demonstrated by the outcome specified for ‘governance’:

Managerial and clinical leadership and accountability, as well as the organisation's culture, systems and working practices ensure that probity, quality assurance, quality improvement and patient safety are central components of all the activities of the health care organisation.²⁴

National Service Frameworks are considered part of the developmental standards of SfBH, and the NHS and local authorities need to demonstrate they are progressing towards achieving the service quality described in them too. NSFs were launched in April 1998, as a rolling programme of national standards designed to address unacceptable variations in health services. They identify key interventions for particular services or care groups. By

Table 46.2 Clinical governance: a brief history.

Date	Event
1948	NHS founded: In its first 40 years, quality improvement initiatives had mixed success; efforts to improve the quality of patient care remained fragmented and disparate.
1980s	Managers and policy-makers tried to apply industry-based approaches of total quality management (TQM) and continuous quality improvement (CQI). ⁹ Initiatives not widely accepted within health service organizations.
Early 1990s	Medical and clinical audit introduced, but criticized as being dominated by medical professions. Benefits not readily apparent to the wider health service or to patients. ¹⁰
End of 1990s	Public confidence in the NHS undermined and serious doubts raised about the quality of care available to patients. A series of clinical and organizational failures, included bone tumour diagnosis in Birmingham, UK, and paediatric cardiac surgery at the Bristol Royal Infirmary. ^{11, 12} Small number of clinicians continued to practise, while their poor performance and professional conduct was tolerated by colleagues and went unchallenged by regulatory bodies. ^{13, 14} Urgent action required to systematically address the quality and safety of patient care across all NHS organizations. Systems and processes were failing when credible individuals were able to do incredible things to patients to whom they had a duty of care. ¹⁵
1997	The NHS policy paper, <i>The new NHS modern, dependable</i> was published. ¹⁶
1998	The consultation document, <i>A first class service: Quality in the new NHS</i> was published. ¹⁷
1999	NHS Executive Health Service Circular, <i>Clinical governance: Quality in the new NHS</i> was published. ¹⁸
1999	Health Act ¹⁹ made ‘quality’ a legal duty and introduced corporate accountability for clinical and organizational performance across the NHS. The concept of clinical governance was introduced and implemented. Every NHS Trust chief executive became ultimately responsible for assuring the quality of healthcare services provided by their organization

2006, there were NSFs for mental health, coronary heart disease, older people (including stroke), paediatric intensive care, children, diabetes, long-term conditions, cancer and renal services.²⁵

Other standards are produced by the Medical Royal Colleges and the General Medical Council, while guidelines and advice specific to ENT are issued through organizations, such as the British Association of Otorhinolaryngologists, Head and Neck Surgeons (BAOHNS), the British Association of Head and Neck Oncologists (BAHNO) and the Department of Health (www.entuk.org; www.bahno.org.uk/bulletin.htm; www.dh.gov.uk).

A nationwide body, the National Institute for Health and Clinical Excellence (NICE), was set up in 1999 for the appraisal of new and existing health treatments (for example, drugs and medical devices).²⁶ NICE provides guidance on clinical procedures and develops clinical guidelines for disease management. For example, in June 2006, guidance was published on the use of the ultrasonic scalpel in tonsillectomies and in July, on tonsillectomy using laser.^{27, 28} NICE also uses evidence about clinical effectiveness and cost effectiveness to inform decisions in the health sector.

Seven national collaborating centres have been established by NICE; one of which helps develop clinical guidelines and service guidance for the NHS in England and Wales on cancer treatment and care, including head and neck cancer. Guideline development groups are composed of doctors, other health professionals and patient/carer representatives.²⁹ The Healthcare Commission sponsors a head and neck cancer audit, part of the National Clinical Audit Support Programme (NCASP). The aim is to deliver risk-adjusted, clinical audit data for head and neck cancer treatment centres in England through the Data for Head and Neck Oncology (DAHNO) audit service.³⁰ Clinical audit is an important component of clinical governance. In 2006, the Chief Medical Officer cited clinical audit as one of a number of quality improvement methods necessary to ensure good clinical governance and a valuable tool for clinical engagement in quality assurance and improvement. However, he also acknowledged that not only does it fall short of its potential (it needs 're-energizing' locally), but there are concerns about the lack of mechanisms for findings of local clinical audits to be systematized into national service improvements.³¹ Head and neck cancer services are receiving local feedback reports from the DAHNO with the intention that collecting these data will enable comparative analyses to be made of cancer services across England and the identification of those areas where the quality of patient care could be improved.

Monitoring and inspecting clinical governance

As part of the greater emphasis on quality assurance and improvement, and patient safety in healthcare, a

monitoring and inspection system was put in place in November 1999 to independently regulate NHS performance in England and Wales. The Commission for Health Improvement placed the clinical governance arrangements of all NHS trusts under its scrutiny and completed clinical governance reports on each trust. CHI review teams looked at the effectiveness of the policies, systems and processes an organization put in place to deliver clinical governance, gathered data on patient care and gained the views of staff, patients and carers. It also conducted investigations into serious service failures, including the unacceptable performance and behaviour of individual clinicians. NHS employers may initially refer a poorly performing doctor to the National Clinical Assessment Service (NCAS) which assesses concerns about doctors and offers advice (www.ncas.nhs.uk).

In 2003, CHI became responsible for publishing NHS performance ratings. All NHS trusts were rated from zero to three stars based on data collated by CHI, including each trust's clinical governance report. These star ratings were replaced by an annual health check in 2005 after an independent body with statutory powers, the Healthcare Commission superseded CHI.

Under the 'health check', each NHS Trust Board in England is required to produce an annual report in which it rates the extent to which its services meets the 24 core standards of SfbH.³² This annual rating of performance has two parts: one looks at the quality of services available to patients and the public; the other at trusts' management of finance and other resources. The system is one of self-assessments, although the focus on the quality of an organization's leadership and management and other key elements of clinical governance are retained.

The Healthcare Commission has made the interests, welfare and experiences of patients paramount among its concerns and adopted a patient-centred approach to improvement in the quality of the NHS and independent healthcare. It has an integrated approach to assessing the standards of services provided for patients and carers and its remit concentrates the functions of what were several organizations, into one. This includes:

- coordinating inspection by registering and inspecting private and voluntary healthcare services, including private hospitals and exclusively private doctors;
- national studies of the efficiency, effectiveness and economy of healthcare;
- production of clinical audit tools to support clinicians in their local clinical governance and audit activities;
- independent assessments of patient complaints and arrangements in place for promoting public health;
- joint inspections of integrated health and social care services with the Commission for Social Care Inspection (CSCI) (from 2008, the HC and CSCI will merge);
- working with the Mental Health Act Commission to assess the provision of care in mental health (the

Healthcare Commission is expected to take over many of its functions in 2007);

- surveys of patients' and users' experiences of healthcare.

The National Patient Safety Agency

Clinical governance has been recognized as a key driver in improving the safety culture within NHS trusts.³³ The National Patient Safety Agency (NPSA)³⁴ was set up in 2001 to build a safer NHS, promoting an open and fair culture in which patient safety incidents and 'near misses' from across the NHS would be reported, collected and acted on to improve the quality and safety of care for patients. The NPSA also aims to initiate preventative measures so healthcare organizations nationally can learn from these reports, as well as from the mistakes and problems that affect patients' satisfaction. Although most information is extracted from existing local risk management systems, an online form allows health professionals across England and Wales to report directly to the system and retain anonymity.

The agency's work also includes safety aspects of hospital design, cleanliness and food, as well as having responsibility for research ethics committees and the National Clinical Assessment Service.

By early 2005, all NHS trusts were linked to an NPSA National Reporting and Learning System (NRLS), although by 2006 the lack of timely deliverance of the system was the subject of a number of critical reports.^{33, 35} There remained a lack of accurate information on serious incidents and deaths; at least 35 trusts had not submitted data and trusts were provided with only limited feedback and solutions to reduce serious incidents. Few trusts formally evaluated their safety culture so incidents were not being seen as opportunities for learning that prevent reoccurrence.

These findings were reiterated in the Chief Medical Officer's proposals for doctors' regulation and patient safety. By 2006, the systematic attempts to improve adverse event detection were still 'in their infancy' and events were still not reported by healthcare workers because of fear of blame.³⁶ Not only was under-reporting of incidents still a problem, but doctors were less likely to report an incident than other staff groups. The Healthcare Commission's 2006 report on the state of healthcare also expressed concern that there was no reliable information nationally about the avoidable deaths of patients and about serious injuries. It is, therefore, to work with the NPSA and others to improve the collection, analysis and action around reported patient safety incidents.³⁷

Assuring the quality of a doctor's practice

The General Medical Council (GMC) is the regulatory body for doctors who work in the UK. It sets the

educational requirements for entry on to the medical register and the professional standards expected of doctors once they are on it. These professional standards are made explicit in *Good medical practice*,³⁸ which describes the principles of good practice and standards of competence, care and conduct expected of doctors in all aspects of their professional work. Serious failure to follow the guidance will put registration at risk.

At the time of writing the GMC is undergoing the most extensive reform of medical regulation since it was founded in 1858. Part of these reforms is intended to ensure that clinical governance systems are joined up and effective through the maintenance of high standards of professional practice and patient protection. The GMC oversees the quality assurance of standards of practice. It is the duty of doctors to promote patient safety and to take part in systems of quality assurance and quality improvement,³⁸ that is, to participate in activities related to clinical governance. The GMC, however, has been the subject of mounting criticism over its inability to adequately safeguard high standards of patient safety and care.³⁹ A number of investigations into the practice of individual doctors, culminating in Dame Janet Smith's inquiry reports into the murders committed by Dr Harold Shipman, showed both a 'past culture of inaction' and a 'conspiracy of silence', whereby well-known concerns about a doctor were denied or avoided and the interests of the patient were subordinated to other considerations.⁴⁰

The concerns expressed in the fifth report of the inquiry⁴¹ led to the postponement of the launch of doctors' revalidation (a system, including annual appraisal, to enable doctors to have their licence to practise renewed every five years) – and the commissioning of the *Good doctors, safer patients* report. The latter report advocated a new approach to promoting and assuring good medical practice and to protecting patients from bad practice. A radical reshaping of the role, structure and functions of the GMC was proposed with increased lay representation and public accountability. The report also recommended that educational and standard-setting bodies for doctors be given a more formal role in medical regulation. Among the needs it addresses are to:

- design an effective interface between local healthcare systems for assuring good clinical governance and patient safety and the system of regulating the practice of individual doctors;
- introduce an effective system of regular assessment of doctors' practice which overcomes the weaknesses in earlier revalidation proposals;
- create standards of medical practice that are transparent and capable of assessment;
- develop methods of assessment that can measure a doctor's performance against a predetermined standard;
- reduce the climate of blame, retribution and disciplinary action that usually attends poor medical

performance and introduce stronger elements of prevention and earlier recognition of problems, retraining and rehabilitation;

- eliminate situations where poor practice is not recognized and acted upon because of adverse organizational culture and weak local clinical governance.⁴²

Future measures will be implemented within a developing environment which recognizes that, inevitably, even good doctors make errors, which encourages open discussion and honesty about performance of individuals and clinical teams and which recognizes the importance of professional accountability for delivering care that is safe for patients and of high quality. Such an environment, in which weaknesses can be identified and individuals can be helped to learn and improve, rather than be blamed, may offer the best chance for sustained quality.

Underpinning all of the above is the maintenance of clinicians' professional knowledge and skills through professional development, improved access to information and communication technology and evidence-based research to support patient treatment and care.

Good medical practice also stipulates that it is the duty of a doctor to put the care of patients first, to listen and respect their views and to respect the rights of patients to be fully involved in their care. Relationships with patients should be based upon openness, trust, good communication, politeness, honesty and consideration.

PATIENT AND PUBLIC INVOLVEMENT

The NHS of the past 'has been characterised by paternalistic providers and compliant patients'.⁴³ Clinical governance, however, aims to change this and put the patient at the centre of delivery of their care.

Robinson and Dixon⁴³ acknowledged the changes of culture occurring in the NHS. Over the last decade, there has been a radical change in public knowledge and attitudes towards health. As healthcare consumers, patients have expectations that: information will be readily available about the service they are being offered; their consent will be gained prior to treatment; they will be respected; and they will be genuinely involved in services.

In 2003, the Isaacs Report provided evidence that as part of medical research programmes undertaken in Manchester, UK (1985–1997), the organs and tissues of hundreds of people were retained from coroners' post-mortems and community mortuaries without relatives' knowledge or consent. These practices were carried out in the belief that they were 'in the public interest'.⁴⁴ Practices carried out 'for the public', but without their consent are no longer acceptable. Seeking consent is an essential feature of good clinical practice.

The availability of health information for patients is due, in no small part, to the internet. Many patients and

carers in the UK and elsewhere have access to an ever increasing number of public-friendly health websites. As people become more knowledgeable, they are more able to make informed choices about their care and gain recognition from healthcare professionals that the patient is a partner in making treatment choices and not simply a passive recipient who takes what they are given.

In January 2003, a statutory duty was placed on every NHS organization to involve and consult patients and the public in the ongoing planning and provision of NHS services.⁴⁵ The NHS Community Health Councils, representing patient and public interest in the NHS, were replaced by Patient Public Involvement Forums, designed to give the public a voice in decisions that affect their health and that of their community. These provide a useful contact point for health professionals who seek public involvement and representation, for example when planning and designing new ENT services. In addition, Patient Advice and Liaison Services (PALS) were introduced in trusts for 'on the spot' support to patients, carers and their families with concerns relating to their care and treatment, and to provide information on the NHS complaints procedure.

The Commission for Patient and Public Involvement in Health (CPPIH) set up in January 2003 to support and manage the patient forums, and the forums themselves, are to be replaced by Local Involvement Networks (LINKs), to be established for every local authority with social service responsibilities. *A stronger local voice*⁴⁶ sets out these plans for the future of patient and public involvement (PPI), giving people a greater say in health and social care service provision, consultation about changes to services and about design of new services.

In addition, the NHS Centre for Involvement was established in 2006 as a 'one-stop shop' for information and advice on PPI.⁴⁷ This aims to support the development of local PPI networks for professionals, patients and the public by providing practical resources and information. In order to promote, lead and support sustained patient and public involvement across the NHS, it will work with PPI advocates from diverse sectors of the community including from PPI forums (whilst they continue), voluntary and community organizations, statutory authorities and local authority Overview and Scrutiny Committees (OSCs). (The latter scrutinize the activities of organizations that provide local health and social care services to see whether services are appropriate to local needs.) The OSCs should be consulted if there are major changes or variations to health services in the community, and, subject to legislation, will be encouraged to focus their attention on the work of commissioners of services.

Patient and public involvement in ENT

The care of patients is the primary concern of a good doctor.³⁸ In head and neck surgery, as across all

specialties, if patients are to be at the centre of care, then professionals need to be accountable not only to their colleagues, their professional colleges and associations, but directly to the patients themselves. The BAOHNS guidance on clinical governance goes as far as to state, 'Clinicians should hold themselves accountable to their patients first and their profession second.'⁴⁸

Patient-centred care in ENT involves:

- working well with other professional groups and disciplines across health and social care, to meet patient needs as a whole;
- openly exploring treatment options with patients, including patients' preferences and personal circumstances;
- involving patients and carers in decision-making;
- responding to patients' needs for clear information about their care and understanding of what the treatment process involves;
- listening to patients and carers and answering their questions honestly, directly and sensitively;
- recording at every stage of the care process;
- communicating diagnosis and treatment decisions quickly to the patient's general practitioner (GP) and to other professionals involved in their care;
- involving patients and the public in all aspects of monitoring and developing the service.

An example of patient involvement in service development concerns cancer care standards used by clinicians. Birchall *et al.*⁴⁹ involved 40 head and neck cancer patients and 18 carers in a series of focus group meetings. They showed that although participants' views differed substantially from the professionals, the patients generated information that translated into improvements in existing national, professionally derived, standards of care for head and neck cancer (2000 national consensus standards).

The above patients' views may have differed from those of professionals, but differences may also occur when patients, carers and the public are asked what should be done to improve health services. A team of health professionals on a Clinical Governance Development Programme sought patients' and carers' views about the service they provided and how it could be improved. They did this through interviews, questionnaires and workshops. Repeatedly, patients and carers came up with the same concerns about the hospital environment, in particular the state of the waiting room and a lack of decent drink facilities. The team of professionals were perplexed by the responses they received because they expected patients and carers to be concerned about the same things as staff, that is, the clinical aspects of care.

Similarly, when the public were surveyed about the assessment of doctors for *Good doctors, safer patients*,⁵⁰ they wanted a doctor's assessment to go beyond their technical skills and whether or not the doctor was up to date. They placed a high value on interpersonal qualities

such as communication, respect, affording patients dignity and involving patients in treatment decisions.

Understanding that patients and carers are likely to have a different viewpoint about what constitutes high quality and safe services is key to effective clinical governance in ENT, as in all services.

THE NHS CLINICAL GOVERNANCE SUPPORT TEAM

The team of health professionals in the hospital environment example above was attending a programme run by the NHS Clinical Governance Support Team (CGST).⁵¹ The CGST was set up in 1999 to help implement and embed clinical governance in the NHS at a local level and support the delivery of high quality, patient-centred care. It also aims to improve awareness and understanding of clinical governance across and throughout NHS organizations, by acting as a focus of expertise, advice and information on clinical governance.

Until 2005, much of the CGST's work focused on delivering a series of national development programmes and activities designed for multidisciplinary healthcare teams and the board teams of NHS trust organizations.⁵² The CGST's earliest activity was to establish a Clinical Governance Development Programme that supported multidisciplinary teams of frontline NHS staff to review their local services and to implement changes in healthcare quality for patients and for staff. In addition, there were programmes for trust boards to ensure that strategic leadership and clinical governance were high on the board's agenda, and a programme, utilizing learning from the aviation industry, to establish effective team-based working through training 'team coaches'. A website at www.appraisalsupport.nhs.uk was also established to provide appraisal support and a discussion forum for all doctors, regardless of specialty. This developed out of an earlier general practitioner appraisal programme which trained GPs across England as appraisers. The CGST continues to be a source of expertise on patient and carer involvement for frontline NHS staff and supports more effective means of engaging patients and communities in their local services.

In 2006, the work of the Clinical Governance Support Team became the subject of review. Its main development programmes ceased in 2005, although two modular e-learning programmes were established for community pharmacists and primary care managers. The CGST also worked to follow up the clinical governance aspects of the Shipman Inquiry⁴¹ and to support medical appraisal and revalidation for all doctors.⁵³ Two further workstreams provided customized support to referred NHS organizations operating under challenging circumstances and worked with a small number of trusts to identify 'known' leaders and establish a team of people with the skills to drive through clinical governance improvement projects.

Developing teams and supporting the way that they function as units has been an important aspect of CGST work. Team development continues to be a difficult task in the NHS, especially where there have been barriers between different professional groups, multiple lines of management, perceived status differentials and a lack of organizational systems and structures for supporting and managing teams of people working together. ENT is a specialty that often brings people together to work in multidisciplinary and multiprofessional ways involving, for example, oncologists, audiometricians, maxillofacial surgeons, speech and language therapists, and so on. A poorly functioning team can not only undermine clinical performance, but also compromise the safety of the patients in its care.

MULTIDISCIPLINARY TEAMWORKING

The philosophy of clinical governance has patient safety at its very core. Delivering care that is both high quality and patient-centred must, of necessity, also be safe.

Poor team-working can endanger patient safety^{54, 55} and put patients' lives at risk,⁵⁶ whereas effective teamworking has been linked to lower patient mortality.⁵⁷ As treatment programmes become more complex, patient safety is ever more dependent on the effective, collaborative working of multidisciplinary teams.

Good medical practice recognizes that most doctors work in teams with colleagues from other professions, that the skills and contributions of colleagues must be respected, communication must be effective and that team roles and responsibilities should be understood by both colleagues and patients.³⁸

Modern healthcare is increasingly complex and requires coordinated and integrated delivery, none more so than in the treatment of cancer patients, where care can be poorly coordinated and confusing for those patients who experience both a wide range of services and different professionals involved in their care pathway.⁵⁸

Multidisciplinary team-based working is a way of tackling this potential fragmentation of patient care. There is growing evidence that it makes a critical contribution to the delivery of effective, innovative and safe healthcare in the NHS.^{54, 57}

The 1995 Calman-Hine Report on Cancer Care supported the widespread establishment of multidisciplinary teamworking across all cancer professions to address patients' needs from diagnosis onwards. The underlying principles for cancer services developed in the report were based on high quality, localized, accessible and patient-centred care. A follow-up review of the implementation of the Calman Report showed that of a sample of 22 trusts/hospitals visited, MDTs who reported as meeting regularly, usually using case notes, were increasingly the norm in cancer care. However, differences between the nine common cancers were highlighted.

Whilst 85 percent of breast cancer teams regularly met to review patients, only 45 percent of head and neck MDTs did so.⁵⁹

Birchall *et al.*'s 2003 study⁵⁸ identified a shift towards multidisciplinary teamworking in head and neck cancer in the UK, although there was some indication of differing work patterns within teams, multiple teams in the same hospital and overlapping teams. This begs the question, what is a team? Many practising head and neck surgeons consider themselves to be working in teams, but what passes as a team, particularly a MDT, may be neither multidisciplinary nor a team.

Mohrman *et al.*⁶⁰ have defined a team as:

... a group of individuals who work together to produce products or deliver services for which they are mutually accountable. The team members share goals and are held mutually accountable for meeting them, they are interdependent in their accomplishment, and they affect the result through their interactions with one another. Because the team is held collectively accountable, the work of integrating with one another is included among the responsibilities of each member.

Case study 1 illustrates the benefits for the patient, their carers and the professionals involved, of making a 'team' in a head and neck cancer clinic in a NHS trust in England (a team more like John Shaw's) into an effective, well-functioning MDT. Working from a multidisciplinary combined oncology clinic or team has many advantages, including:

- increased continuity of patient care;
- reduced multiple appointments with different professionals;
- increased professional knowledge and understanding through pooled expertise;
- development of professional peer support and communication;
- cost-effective use of time and resources;
- individual consultants being accountable and not working in isolation;
- decisions being audited and treatment aligned with agreed procedures;
- reduced likelihood that mistakes and errors are hidden and will reoccur.

GOOD PRACTICE CASE STUDIES

Case study 1: Making the team multidisciplinary

Case study 1 illustrates part of a broad portfolio of clinical governance activities being undertaken in local organizations across the NHS to improve patient safety and care.

HOW THINGS WERE

- A typical head and neck cancer team was made up of single surgeons (e.g. ENT, maxillofacial, plastic) who worked surgically alone, with occasional help from colleagues.
- Surgeons referred patients to radiotherapists for radiotherapy after surgery, or if unable to perform surgery, for radiotherapy.
- Patients were clinically treated in parallel rooms at best, in different hospitals at worst.
- Clinicians ran different clinics and were largely unaware of colleagues' activities.
- Managers tried to encourage more multidisciplinary activity (as recommended by the NHS Cancer Plan, 2000⁶¹). They initially suggested the team met at lunchtime to minimize the effect on clinical activity.
- Minimal equipment for viewing radiology images and histopathology specimens was available at such sessions and there was 'no regular room availability' to accommodate such meetings.

- The team attending the patient now 'sing to the same hymn sheet'.
- Younger members of staff can seek advice and discuss patient care.
- Allied health professionals attend weekly meetings in increasing numbers.
- A clinic nurse coordinator was appointed to ensure that histopathology and x-ray results are available on the day, that patients have been informed that their case will be discussed and that they can attend the subsequent clinic.
- Patients are no longer inconvenienced by a time delay in decision planning. Only new patients, planned postoperative patients and more difficult patient cases are seen in a 'controlled environment'.

It has been agreed that in such a clinic environment, we agree on one principle: that we need a combination of good communication and effective team working to get results.

Consultant

WHAT WAS DONE

- Some specialists work across specialties and locations and MDT meetings are often difficult to schedule outside normal clinical working hours.
- Most clinicians attended an 'old style' weekly combined head and neck clinic for one to several hours. They decided to have the MDT meeting as a part of the normal head and neck clinic and discuss problem and new patients.
- Patients who had been discussed or who had previously agreed a combined treatment to include radiotherapy would be seen following the MDT meeting, in a combined clinical MDT environment.

Case study 2: Improved pathways for children with grommets

As the second case study shows, by addressing the needs of patients when building services, and considering how their journey through the care pathway may be reduced, it is possible to make changes which not only improve the patient experience, but improve the experience of healthcare professionals too.

HOW THINGS WERE

- A child with grommets inserted as treatment for secretory otitis media (glue ear) was examined by the ENT consultant about six weeks after surgery.
- The consultant checked that the grommets were still in position and infection had not set in, before sending the child to the audiologist for a hearing test.
- There were follow-up visits to the consultant to check the grommets; each required a test to ensure hearing gain had been maintained.
- The audiometrician or audiological scientist was not involved in the patient's examination or party to the consultation.

WHAT HAPPENS NOW

- The MDT meeting has a planned structure and is executed 'like clockwork'.
- The MDT usually meets in a room in the radiology suite. A move closer to the clinic is planned, to improve transit time from the MDT meeting to the MDT clinic.
- The case for each patient (most are recently diagnosed) is presented by each team leader to an audience of peers and medical students.
- Clinical pictures prior to biopsy, radiology and pathology are shown and each patient's management is openly discussed.
- The diverse group assembled may include surgeons, pathologists, radiologists, physiotherapists, dieticians, speech and language therapists, Macmillan nurses, the pain management team and social workers.
- A consensus is recommended and agreed prior to the patient's treatment.

WHAT HAPPENS NOW

- Despite some resistance to change, a new process was implemented.
- The audiologist runs a clinic in parallel with the consultant, examines the child, takes a history from

the parent, performs and interprets the post-grommet insertion hearing test.

- If results are normal, an audiometrician or an audiological scientist recommends further management of the child following agreed practice guidelines. This allows for direct patient/parent feedback there and then.
- If hearing is abnormal, the consultant can see and review the patient at the same session – sometimes even in the audiology booth.
- If the grommets have been rejected, the tympanic membrane is intact and hearing is satisfactory, the child is discharged back into the care of their family doctor.
- The new process means at least two visits to the doctor are cut out; clinic slots that can be reused, so that new patients can be seen sooner.

CONCLUSION

Standards for better health reiterated that 'quality' is at the forefront of the agenda for the NHS and for private and voluntary providers of NHS care.²³ Clinical governance is integral to this agenda, but is in need of further development if it is to be effective. In 2006, the chief medical officer stated that:

The culture of clinical governance needs to be spread to more local NHS organizations, there needs to be more consistent adherence to best practice standards and guidelines; more information on quality of care should be available to patients; and more effective and timely learning from adverse events needs to take place.⁶²

The fundamental challenge in implementing clinical governance is to achieve this culture, which for many requires a transformation of ways of working, of attitudes towards others and of systems at the level of local NHS organizations.

Clinical governance invites the re-examination of traditional ways of working within health services. It questions existing professional, organizational and cultural boundaries. It questions individuals like John Shaw, since, when appropriately applied, it is a way of working and a way of rethinking professionalism and partnership with patients. The appeal and impact of clinical governance lies in a 'whole systems' approach to improving the quality of patient care. It is essential for organizations to have effective systems and processes in place for clinical governance to be delivered, but these alone are not sufficient. Organizations are only as good as the people who work in them. The true mark of successful implementation is when clinical governance is embedded to the extent of it being 'the way we work around here'.

NOTE

The information in this chapter, particularly with regard to the work of the NHS Clinical Governance Support Team and other national bodies associated with delivering the quality and safety agenda, is subject to change beyond 2007, following a period of review. However, the principles of good clinical governance remain applicable to all involved in continually improving patient safety and care.

For the latest clinical governance information, see the CGST website at www.cgsupport.nhs.uk.

KEY POINTS

- It is the duty of a doctor to promote patient safety and take part in systems of quality assurance and improvement.
- Clinical governance provides the framework by which NHS organizations work to improve and assure the quality and safety of clinical services.
- It is supported by systems established to improve standards and to monitor and inspect the quality of services for patients.
- Clinical governance puts the patient rather than the professional at the centre of care.
- A national Clinical Governance Support Team helps implement and embed clinical governance in the NHS.
- A poorly functioning team can undermine clinical performance and compromise patient safety.
- Multidisciplinary team-based working makes a critical contribution to the delivery of effective, innovative and safe healthcare.

Stopping treatment	587		

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words medical ethics, bioethics, duties and responsibilities, consent, refusal, confidentiality, withholding and withdrawing treatment, resource allocation and research ethics.

INTRODUCTION: WHY DO WE NEED MEDICAL ETHICS?

We live in a multifaith, multicultural society. In this pluralist context there is a lack of moral consensus. People do not necessarily share a common moral outlook and determining what is right and wrong is based on a variety of different values and value systems. Not only do different individuals hold different moral views, e.g. an atheist and a Muslim, but one person may draw on different and even contradictory moral values in him/herself, e.g. naturalism and a technological imperative. In medicine, these differences lead to disagreement both in practice and theory between doctors, other professionals, patients, families and institutions. Difficult cases highlight the differences in moral perspectives and pose challenges for determining a ‘best’ or ‘right’ way forward.

In response to these difficulties, theoretical ethics provides a framework for approaching complex dilemmas and difficult decisions. Ethics does not provide easy answers to difficult problems, but it offers a clear structure and more consistent means of making moral

decisions. On the practical level, ethics is not something which is outside medicine, but it is an integral part of doctors’ daily practice, whether in relation to gaining a patient’s consent, observing confidentiality or using professional judgement to assess areas such as best interests. It offers critical analysis of difficult issues and guidance in making decisions in practice.

THE DOCTOR–PATIENT RELATIONSHIP

The doctor–patient relationship is the context within which many medical ethical dilemmas arise. In the UK and other countries, there has been a general shift from paternalism towards consumerism in medicine. Patients are less willing to accept what the doctor says without question and are more likely to pressurize doctors to do what they wish. Doctors are seen as ‘need-meeters’ who can and should dispense a pill or offer a treatment for every ailment. This poses difficult decisions for doctors in balancing what patients need, want and even demand.

Along with this shift towards consumerism has come an increasing emphasis on individual autonomy and 'rights'. Patients' rights have been enshrined in the Patients' Charter (and the Human Rights Act 1998). This is partly a reaction against the paternalism of medicine where 'doctor knows best' and takes little note of patients' choice, desires or preferences regarding treatment. Respecting patient autonomy is now recognized as a fundamental principle in medical ethics.¹

Rather than watching the pendulum swing from one extreme to the other, a balance can be struck between paternalism and consumerism. Both the doctor and patient have valuable input to provide in any medical consultation. A partnership model allows for the patient to provide information about his/her own body and symptoms, as well as personal choices and preferences, while the doctor brings his/her knowledge, skills, expertise and experience to the individual case.² Together they are able to determine the best way forward for this particular patient. This partnership model requires good communication on both sides and recognizes the role of duties and responsibilities in medicine.

DUTIES AND RESPONSIBILITIES OF DOCTORS

Duties and responsibilities of doctors go back as far as the Hippocratic Oath and are set out in professional codes of conduct.^{3, 4, 5} These codes highlight both the positive and negative duties doctors have to their patients, colleagues, institutions and wider society. Duties and responsibilities are fundamental to the practice of medicine and include nonmaleficence, beneficence, respect for autonomy and justice.¹

Doctors have a negative duty of nonmaleficence, or doing no harm, to patients. Both professionally and ethically doctors have a responsibility not to harm their patients. A doctor may harm his/her patient by being negligent or not following correct medical procedures. Yet, it is difficult to uphold nonmaleficence in its literal sense as doctors may inflict initial harm on patients in order to achieve good in the end. This is not doctors being negligent or unethical in their practice. Patients who undergo head and neck surgery experience initial harm and pain, but the aim is to bring about cure from disease. This harm is unavoidable and if doctors could cure the patient through other, less harmful, means then they would. The long-term benefits of cure outweigh the short-term detriments of medical intervention. The intention and motivation of the doctor, as well as the results of a treatment, are crucial in assessing the harm done to patients. Some degree of harm may be unavoidable in order to cure a patient and justifiable if the good done is expected to outweigh the harm.

The danger is that nonmaleficence may be simply defensive. In contrast, beneficence is proactive and is

about doing good to patients. Not only are doctors to refrain from harming their patients whenever possible, but they also have a duty to do good to them. The most obvious way of fulfilling this duty is to cure a patient of his/her illness, disease or dis-ease and restore him/her to full health. Cure is not possible in all cases. Both doctors and patients should recognize the reality and the limits of medicine. In some cases, limiting the harm done by a disease or illness may be the best doctors are able to do. Beneficence extends beyond cure and includes caring for patients and treating them with respect and dignity.

Part of doing good to patients involves respecting their autonomy. Autonomy literally means self-rule and is understood as self-determination and choice. In health care, respecting autonomy generally means allowing patients the freedom to make decisions for themselves, even if doctors disagree with those choices. A patient might refuse curative maxillofacial surgery because of the degree of disfigurement caused even though doctors advocate it.

In modern western societies, the autonomy of individuals is frequently emphasized. The ability and freedom to make our own choices is paramount. This carries over into health care too. Considerations of autonomy highlight at least two points within medicine. The first is that patients are not the only people who possess autonomy. Doctors, nurses and other professionals also have autonomy which can and is exercised. For example, a doctor cannot be forced to give a treatment against his/her professional judgement. The second is that in any society or community, individual autonomy is always limited. Autonomy is limited if there is a risk of, or actual, harm to oneself or others. If a patient is suicidal, he/she can be sectioned to avoid harming him/herself. If a patient attempted to attack someone on the hospital ward, then his/her autonomy would be restricted to prevent harming others. For all of us within health care and society more generally, autonomy is limited. Legislation in dealing with the threat of infectious diseases shows that an individual's freedom and autonomy can be limited if the risk to others is great.

Part of doing good to patients and respecting their autonomy involves being just. Doctors have a duty to treat individual patients fairly and equally. This means treating similar cases in similar ways and dissimilar cases in dissimilar ways. Both types of justice ensure there is a minimum standard of consistency in interactions with all patients.⁶ Fairness and equality do not allow doctors to discriminate against patients based on clinically irrelevant factors, e.g. religion, race, sex. Doctors not only have to weigh up considerations of justice in relation to individual patients, but also between all of their patients.

These key responsibilities of nonmaleficence, beneficence, respect for autonomy and justice are four of the fundamental principles in medical ethics and practice. In

recent years these have been seen as the key principles that provide the foundation for doctors' duties in medical ethics. It can be argued that other ethical duties are significant in medicine. That these principles are necessary in medicine is generally agreed, but whether they are sufficient is debated.⁷

In looking beyond these four principles, doctors also have a duty to care. This duty is fundamental to each and every interaction a doctor has with patients. It is the basis from which doctors begin and carry out their work. For the doctor, this involves looking after patients to the best of his/her ability and applying his/her knowledge, expertise and skills to care for the patient.

Part of this duty to care includes protecting the best interests of the patient. Doctors have a responsibility to act in the best interests of their patients. This does not mean that doctors make decisions about best interests without reference to or discussion with the patient. Yet, deciding what is in the best interests of the patient may not be straightforward depending on how and when best interests are defined and who defines them, e.g. doctor, patient, relatives or other professionals. Doctors may not agree whether surgery, radiotherapy or chemotherapy is in the best interests of a child with a neck tumour and the patient and parents may also have differing views.

When examining the duties of doctors, there may be a problem over who defines best interest and how it is defined. There is also a difficulty when different duties and responsibilities conflict, e.g. nonmaleficence and beneficence. Analyzing how to proceed and which responsibilities take priority are key questions in medical practice. A hierarchy of duties may be required to clarify priorities and aid decisions in practice. For example, it might be argued that doing no harm is more important than doing good and that the duty of care is fundamental to all interactions with patients.

BASES FOR MEDICAL ETHICS AND MORAL DECISION-MAKING

Individuals make and assess moral decisions on different bases. These form the foundations of our view of what is 'right' and 'wrong'. At their root, such decisions can be primarily based on principles, consequences or virtues or some combination of these.

Principle-based morality

Deontological morality is based on principles. It deals with what we ought to do; that moral obligation arises from fundamental ethical principles. Whenever people use principles to make decisions, it is important to ask, 'from where do these principles come?' There are various

sources from which doctors and patients draw moral principles.

NATURE/NATURALISM

Naturalism argues that by looking at and reflecting on nature moral truths or principles can be discerned. This includes both the natural world and nature of human beings.⁸ In the nature of things and the nature of people, there are moral principles which reason can discern. Goodness and badness are natural features of the world and people. By observing the way the world is and people are, we can see morality in the nature of things and people.⁹ This is closely tied to what we regard as 'normal' function. Where there is damage to the head or neck, the aim of surgical intervention is to restore normal function and enable the natural processes to function without impediment.

Yet, people have different ideas and conceptions of what is 'natural'. These different views may conflict. In fact, doctors often try to put right things that have gone wrong in nature. Medicine struggles against the ravages of nature and tries to prevent natural disease from harming people. It is also clear that medicine and surgery are in a crucial sense fighting against natural disease and breakdown. Determining what is natural, and the implications of a naturalistic moral view, may not be straightforward.

RELIGIOUS MORALITY

Religion also provides a key source of moral principles. Christianity, Islam, Judaism, Buddhism and Hinduism all teach certain fundamental moral precepts.¹⁰ These are usually enshrined in moral and religious codes such as the Koran and the Ten Commandments. There may be debate about whether such principles are independently valid or dependent on being a follower of a particular religion, but the problem for medicine is whether the different religions all support the same principles or whether they are fundamentally different. At first glance, the Jehovah's Witness refusal of blood transfusions is very different from the ready acceptance of life-saving treatments by other religious groups. Different religions seem to offer different moral principles.

KANT

The philosopher Immanuel Kant also emphasized the role of principles in his highly influential contribution to moral thinking. For Kant, morality is about asking, 'What ought I do?'¹⁰ In response, he tried to identify fundamental principles, or maxims, of action that all people ought to adopt. The key moral principle is the Categorical Imperative, which states 'Act only on the maxim through which you can at the same time will that it be a universal law.'¹¹ The key test for moral principles is whether they

are universalizable, i.e. anyone in the same moral situation would necessarily make the same choice. This is a check against begging the question in your own favour or being biased. Essentially, medical treatment ought to be given to every individual without bias.

For Kant, morality involves respect for people. This respect is based on the intrinsic worth and dignity of human-beings. He requires that we treat humanity, whether ourselves or any other, never simply as a means, but also always as an end.¹² People are ends in themselves. We cannot do medical experiments on people for the benefit of future generations without their consent. That would be using people for some other end than for their own good. Kant's ethics involves moral duties, which apply to ourselves and others. He argues that we have positive and negative moral duties. There are both things we should do as well as those we should avoid, e.g. doctors doing good and not harming patients.

Any morality based on principles may run into difficulties when different moral principles, like duties, conflict. Kant's approach is no exception here. Deciding between principles is often problematic and Kant does not provide a clear way forward. Principles are one key aspect of morality and moral decision-making, but morality also can be based on consequences.

Consequence-based morality

Morality based on consequences is called teleological morality. A consequentialist approach argues that morality should and does focus on the potential outcomes of our choices and actions, particularly in terms of what will happen if we do something against doing nothing at all.

UTILITARIANISM

Utilitarianism is the most well known of consequentialist theories, particularly in health care. It is a moral theory concerned with social reform and it argues that society should adopt laws which make people happy and avoid pain. At the heart of utilitarianism is the Greatest Happiness Principle (GHP), which states that morality is about achieving the greatest happiness for the greatest number of people. If this is the case, then we must have some way of measuring happiness or pleasure. To this end, Jeremy Bentham developed a pleasure calculus.^{8, 13} It includes:

- duration: how long it lasts;
- intensity: how intense it is;
- propinquity: how near it is;
- extent: how widely it covers;
- certainty: how sure we are it will come;
- purity: how free from pain it is;
- fecundity: how much it will lead to more pleasure.

In Bentham's version of utilitarianism, the pleasure or pain of one person, if particularly acute, could outweigh that of many others. To counteract the implicit lack of justice in Bentham's theory, John Stuart Mill introduced the notion of fairness.¹⁴ In assessing pleasure or pain in society, each person should count for one and not more than one. This was an attempt to ensure that the pleasure and pain of each person was weighed fairly against that of others.

Even with the inclusion of justice and fairness, utilitarianism poses difficulties when making moral decisions. One is the danger that the minority will have to sacrifice or forego pleasure for the happiness of the majority and that increasing pleasure may be given a greater moral importance than preventing pain. This view would give equal moral weight to giving people a thrill and alleviating pain. Such critique is particularly important for doctors who are confronted with people who are suffering from illness, disease and in pain.

Underlying utilitarianism, and all consequentialist theories, is a focus on the ends rather than the means of moral choices. But do the ends always justify the means or are there some means which are wrong or immoral in and of themselves and cannot be justified even if they achieve a good end? This question is important in medicine where doctors are weighing up the potential benefits and burdens of treatment. Either doctors or patients may think that the means of achieving a potentially good end are not acceptable, as in the case of some cancer treatments. One critique of a morality based on consequences is that it is difficult to predict, nonetheless control, the consequences of our actions. Doctors are faced with this challenge on a daily basis when treating patients. What they intend to achieve may significantly differ from the end result.

Both morality based on consequences and principles pose problems for doctors. Morality involves an examination of both, but requires more.

Virtue-based morality

In recent moral theory, there have been moves away from a morality primarily based on principles or consequences. The emphasis has shifted toward an appeal to virtues,¹⁵ harking back to Aristotle and Aquinas. Virtue theory focusses on growing virtuous people and asks, 'What is a good person?' It seeks to identify certain qualities and characteristics of a good person and to foster these in individuals. The way that these characteristics are grown and developed in people is in the context of a community.

We may ask, 'What makes a good doctor?' The list of qualities might include having specific scientific knowledge (of disease and illness, as well as treatments), professional expertise and skills, being caring, compassionate, a good communicator and wise. This would affect the selection criteria of would-be medical students.

Then we should ask how these qualities or virtues of a good doctor would be fostered. This would take place within the professional community which trains medical students and newly qualified doctors. Teaching, training and practice are all crucial in the development and fostering of the virtues of a good doctor.

The picture painted in virtue theory is very optimistic. It may not be easy to agree on the characteristics of a good person or good doctor, far less to foster them. Virtue theory does not provide clarity about what to do when these characteristics conflict. In the end, it can seem highly optimistic about how virtuous people really are and how easy it would be to encourage and grow a virtuous person, as well as the nature and role of community in that process.

In examining three approaches to morality, based on principles, consequences or virtues, we have seen that all three harbour difficulties. Perhaps a more balanced view of morality should incorporate considerations of all three – recognizing that principles offer fundamental grounds for making moral decisions, but these cannot and should not be taken without weighing up the potential consequences of any decision. This should all happen within the context of trying to foster the development of virtuous doctors who will be able to make ‘good’ and ‘right’ decisions in practice, based on who they are rather than primarily on decision-making processes.

ETHICAL ISSUES IN PRACTICE

Three approaches to making moral decisions – principles, consequences and virtues – have been examined within the context of the doctor–patient relationship, as well as duties and responsibilities. It is helpful to consider the specific ethical issues in medicine and how we might approach them, rather than simply analyzing the theories of ethics. These include consent and refusal, confidentiality, stopping treatment, ethical issues in research and resource allocation.

Consent and refusal

Consent is fundamental to any and every interaction between doctors and patients. By its nature, gaining and giving consent is a process, not a one-off decision, and patients must be free to change their minds at any point. Consent may be implicit or explicit. A patient may give implicit, or implied, consent by indicating nonverbally that he/she is happy to participate in a procedure, for example holding out his/her arm to have blood taken or opening his/her mouth to have the throat checked. Alternatively, consent may be explicitly stated in verbal or written form. Consent forms provide evidence that a particular process has taken place, but serve only as a minimum standard for recording consent, as they do not

guarantee the quality of communication or level of patient understanding.

The normal standard in medicine is fully informed, valid consent given by a patient who is mentally competent. The ‘fully informed’ part of consent involves the patient being given all relevant information regarding the treatment options and potential consequences of having against not having a particular treatment. In the UK, doctors should provide the competent patient with as much information as he/she needs or desires to make an informed decision.¹⁶ This will vary from patient to patient and doctors are required to use their professional judgement about the degree of detail regarding benefits, risks and burdens in each case. They should assume patients wish to be well informed and use a ‘prudent patient’ standard.¹⁶ This is in sharp contrast to the United States where doctors must make clear any and every known risk, regardless of its likelihood. When attempting to gain fully informed consent, doctors face the challenge of providing sufficient information for a patient to make a decision and telling the truth about the potential risks, over and against allowing patients to keep hope.

To be valid, consent must be freely given, ensuring that patients are free from any improper, undue pressure from doctors or other professionals. How, when and by whom information is given to patients about potential treatment or nontreatment options can have a significant impact on the decisions made. If the consultant emphasizes a particular option as the best course, the patient may be more likely to agree to it. Patients need time to digest the information given to them, ask questions, consult others and weigh up different options.

There are some instances in which (as well as groups of patients for whom) gaining valid consent is a more ethically and practically difficult process. In emergency situations, where patients cannot give consent or refuse treatment, doctors are obliged to act in the best interests of the patient. They have both a legal and ethical duty to take measures to secure the patient’s life and health. These may be short-term interventions that then enable the patient to recover sufficiently to make longer-term decisions about further treatment for him/herself.

For children in the UK, the legal age of consent is 16 years. While the general standard is that parental consent should be sought for medical interventions with children under 16, children should be encouraged to participate in their care and health professionals should act as their advocates.¹⁷ Sometimes, children and young people under 16 may have the capacity to give valid consent. A doctor can give treatment without parental consent if he/she judges the young person to be ‘Gillick competent’ and it is in the patient’s interests.^{17, 18} The former involves assessing whether the child or young person understands the consequences of having against not having a particular treatment or intervention. In reality, the degree of competence required is proportional to the weightiness of the decision. A 13-year-old might be deemed

competent to consent to a tonsillectomy, but not brain surgery.

Individuals who enter the armed forces agree to give up a degree of their individual autonomy and freedoms in the interests of the unit as a whole. They may be called on to put their life and/or health at risk for the good of the service and country. Prisoners also forfeit their autonomy and are less free to give or refuse consent, in particular with respect to intimate body searches. Both groups are still entitled to a high ethical standard of medical care and doctors have the same professional and ethical duties to these patients as others.^{19, 20}

Some patients may be incompetent or lack capacity to make choices and decisions for themselves.²¹ Patients who are mentally impaired or disordered or handicapped may lack sufficient understanding of the nature, purpose, risks and benefits of a proposed treatment to give valid consent. In England, Wales and Northern Ireland, no-one can legally give consent on behalf of a competent adult.^{21, 22} In Scotland, people over the age of 16 may appoint a proxy decision-maker to give consent or refuse treatment for them if they become incapacitated.²³ Doctors should not assume that these patients are incompetent without seeking to engage with them and discern the level of competence. Such patients should be encouraged to participate in decisions about their care whenever possible.

Refusal is at the heart of consent. Patients are free to refuse any treatment or intervention at any time. An adult Jehovah's Witness may refuse a life-saving blood transfusion. If a doctor attempts to treat this patient in the face of a valid refusal, he/she can be charged with assault or battery. Valid refusal requires the patient understands the significance of his/her choice and its implications. The ethical basis for this is respect for autonomy. Patients are free to make their own choices regarding their health care and can even refuse life-saving treatment, regardless of whether doctors agree with them or not. Because of the potential significance of refusing treatment, in reality a refusal requires a higher degree of competency than consent to treatment. Good practice means doctors strive to ensure the patient fully understands the implications of his/her refusal. It should be carefully documented to safeguard the doctor.

Gaining fully informed, valid consent or exploring refusal highlight ethical issues in medical practice. Along with confidentiality, they are fundamental starting points for the doctor-patient relationship and any treatment.

CONFIDENTIALITY

Doctors have a duty to protect patient confidentiality and privacy. Confidentiality matters because it is a key basis for trust between the doctor and patient. In practice, understanding what confidentiality means may vary. Patients may think that in telling their doctor something

in confidence it will not be discussed with anyone else. They may not realize that doctors not only talk to each other and other professionals about particular cases, but the number of health professionals who have access to their 'confidential' medical notes.

Confidentiality involves issues both of truth-telling and disclosure. Doctors have a positive duty to tell the truth to patients and a negative duty not to lie. Without these duties, patients cannot be certain whether to trust what their doctor tells them. Patients expect doctors to give them information and advice which is true and accurate. Not telling patients the truth fundamentally undermines this trust and means that patients' confidence in what their doctor says is eroded.

One argument for not telling patients the truth is that it is sometimes in their best interests. A doctor may decide not to tell a woman with a malignant tumour of the neck that she has cancer. The rationale may be that it would be too upsetting for her. This attitude is paternalistic and assumes that the doctor knows better than the patient how she will cope with the news. If this patient asks for information about her diagnosis, doctors have an obligation to be clear and truthful.

A more difficult area is where patients do not directly enquire about their diagnosis. How much information should doctors give and how detailed should it be? Is it acceptable to be 'economical with the truth'? Information about diagnosis or prognosis should not be forced on patients if they do not want it, but that differs from doctors denying them the opportunity to have this information or patients being given an inaccurate or misleading account of their condition.

There are appropriate and inappropriate ways of telling the truth to patients. A woman with motor neurone disease went to see her general practitioner (GP). She had concerns about her death and wanted to know what would happen to her. The doctor told her she would eventually choke to death. The woman then had recurring nightmares where she would wake up choking. This doctor told the truth, but in a way which was insensitive and inappropriate. There is a balance to be struck between answering questions truthfully and being sensitive to the patient's situation and anxieties.

Any disclosure of information about the patient's condition must be given to him/her first. Doctors should make sure the information and its significance is clear to the patient. Doctors must balance the disclosure of all relevant information to the patient with being sensitive to what the patient does or does not want to know. Patients are free to indicate they do not wish to know certain information, but they should be given the option to decline.

Sometimes relatives believe that they have a 'right' to know details of the patient's condition and pressurize doctors to tell them. Doctors have an ethical duty to protect patient confidentiality and privacy and not to disclose information to relatives without the explicit

consent of the patient. Even though it may put doctors in a difficult position with relatives, patients are entitled to expect doctors not to disclose information about their medical condition to relatives.

There are times when doctors need to consult colleagues about a patient's condition. It is ethically acceptable to share relevant information, even if confidential, in order to determine what care or treatment options are in the best interests of the patient. Good practice ensures that the patient is aware of these discussions and disclosures and the reasons for them. When working in a team, patient information may need to be shared to ensure good and consistent care is delivered. Disclosure at these times should be on a 'need to know' basis and differs from disclosing confidential information which is not relevant to the clinical situation, e.g. the patient's sexual orientation or family situation.

There are some instances where patient confidentiality can be broken without his/her consent. Under the Public Health (Control of Diseases) Act 1984 in England and Wales and the Infectious Diseases (Notification) Act 1889 in Scotland, doctors are under a legal obligation to report notifiable diseases to the appropriate authority.^{24, 25} Ideally, this should be done with the patient's full knowledge and consent and every effort made to encourage the patient to comply. If a patient refuses to agree to the notification, the doctor has a legal and ethical duty to report the disease for the protection of the wider public.

Disclosure in the case of HIV/AIDS poses particularly difficult ethical issues. On the one hand, doctors have to weigh up the potential harm done to patients from disclosing their HIV status against the potential risk of infection to others, like health care professionals or sexual partners. If patients perceive that confidentiality will not be kept, then they may not come forward for testing and treatment. Every effort should be made to encourage the patient to disclose this information him/herself. If this is unsuccessful, disclosure may take place if a doctor believes a specific person, including a sexual partner, is being placed at 'serious and identifiable risk' of becoming infected.^{24, 25, 26}

Data protection and medical records

The Data Protection Act 1984 provides protection of personal information held by others, e.g. medical records on computer. Personal information given for one purpose cannot then be used for a different purpose without consent. The use and handling of this information is restricted. The Act also allows people to have access to personal data at reasonable intervals. Patients can request to have access to their medical notes and read what has been written about them. This has altered both the style and content of what doctors write in the medical notes and the use of medical records for research.

Protecting patient confidentiality and information ensures that trust is maintained between the doctor and patient. When there is a risk of harm to others, doctors may have a duty to break confidentiality. This should be carefully weighed, the British Medical Association or the Medical Defence Union should be consulted and the facts clearly communicated to the patient. The discussions and rationale for breaching confidentiality should be documented.

STOPPING TREATMENT

Withholding and withdrawing treatment

One of the most difficult areas for doctors is deciding when to stop active treatment for an individual patient. There are tensions between whether and when to begin and stop treatment. Whether to withhold or withdraw a medical treatment or intervention, such as chemotherapy, artificial feeding or hydration, can be a contentious area for doctors, other health professionals, patients and relatives. Weighing up the benefits and burdens of treatment, assessing best interests and quality of life are necessary features of such judgements.²⁷

Whether to begin or withhold a treatment is the first phase in this debate. Judgements about withholding treatment should be based on the best available evidence and the individual patient's condition. If the likely burdens and risks of treatment outweigh the potential benefits, the doctor may judge the treatment to be futile. There is much debate about what constitutes futile treatment and who decides, as doctors' and patients' interpretations of futility may differ. In the literature, the generally accepted definition of a futile treatment is one that has less than a 1 percent chance of success.^{28, 29}

If a treatment has been started, there may come a point where doctors believe it should be stopped. The British Medical Association (BMA) document *Withholding and withdrawing life-prolonging medical treatment* offers guidance for doctors in making these decisions. It states that although prolonging a patient's life usually provides a health benefit, doctors are not obliged to prolong life at all costs with no reference to burdens of treatment or quality of life. If a treatment fails or ceases to provide a net benefit for a patient, the justification for providing it is removed and the treatment may, ethically and legally, be withheld or withdrawn (pp. 1–2).³⁰

In practice, doctors may find it more difficult to withdraw than to withhold treatment. To prevent situations where patients are denied treatments which might be beneficial because doctors think it will be too difficult to withdraw at a later stage, the BMA has argued, 'Although emotionally it may be easier to withhold treatment than to withdraw that which has been started, there are no legal, or necessary morally relevant,

differences between the two actions.³⁰ This view is debated.³¹ Philosophically, it can be argued that withdrawing treatment is more like an action (doing something) than an omission (refraining from doing something) and so has a different moral weight and significance.³² Regardless of where one sits within this philosophical debate, in practice there will be cases where it is appropriate to stop or withdraw treatment. Doctors are justified in withdrawing treatment and this does not constitute euthanasia. If treatment is withdrawn and 'nature takes its course', it is the disease which brings about the patient's death, not the doctor.

In the UK, the Tony Bland case has become crucial to the debate about withholding and withdrawing treatment. He was a young man who was seriously injured in the Hillsborough football disaster and was in a persistent vegetative state (PVS). After four years, the doctor and family wanted to remove the nasal-gastric tube through which Tony was being fed. They appealed to the coroner, under whose protection all of the Hillsborough victims were placed, who asserted that he would charge the doctor with murder if he stopped feeding Tony. The case eventually went to the House of Lords and two key rulings were given.³³ First, the Law Lords ruled that artificial feeding was now a medical treatment and, therefore, could be withdrawn. Second, because Tony was in PVS it was not in his best interests to be kept in PVS. Both judgements have been debated and raised issues of withholding and withdrawing treatment among the wider public.

In reaching a decision about whether to withhold or withdraw treatment, good medical practice elicits and incorporates the patient's views and that of the relatives, provided the patient has given permission for that discussion to take place. If doctors are recommending that treatment be withheld or withdrawn, clear rationale and justifications should be communicated to the patient and recorded in the notes. Patients are free to request treatments and some demand particular interventions, but doctors are not obliged to give treatments against their clinical judgement.

Clinical judgements to withdraw treatment should consider futility, best interests and quality of life issues. Doctors have a duty to act in and protect the best interests of their patients. When making treatment or nontreatment decisions, good practice will involve competent patients in that process. For the incompetent patient, the views of the relatives should be sought to ascertain what the patient would have wanted, but doctors are under no legal obligation to do as the relatives wish. Ultimately, the doctor must act in a way which he/she thinks will be in the best interests of the patient. If the patient is a child below the age of consent, then the parents' views are crucial in deciding what constitutes best interests. Even when the child may be deemed competent to consent or refuse treatment, good practice would include the parents in that decision whenever possible.

Similar issues are raised when attempting to assess quality of life. Doctors will have some view of what constitutes a reasonable quality of life, but this may be very different from the patient's view. Competent patients should be given the opportunity to express their view of quality of life issues. For incompetent patients, the relatives should be consulted about the patient's views, but ultimately doctors must make a decision which they believe to be in the best interest of the patient.

RESEARCH ETHICS

Good medical practice relies on a solid knowledge base. This requires good research. The government's emphasis on 'evidence-based medicine' has led to the creation of the National Institute for Clinical Excellence (NICE), which monitors the quality of clinical practice. The rationale for treatments and techniques should be supported by research results and not simply past practice. Research is needed to continue to improve practice and develop new techniques and treatments. However, medical research raises ethical questions for doctors, researchers, patients and the wider community. The nature, content and process of research merit ethical, clinical and scientific scrutiny.

Research can cover a broad range of activities. It can involve tracking a specific genetic disorder in the population or developing a new surgical intervention for hearing impairment. A key aspect of scientific research is that it tests a thesis or hypothesis and that the results are testable and repeatable.³⁴ If the results cannot be tested or duplicated, there is reason to be sceptical about the research. Peer review is an integral and necessary part of all scientific research. This provides a level of scrutiny for the claims and results of research. For a new technique, intervention or therapy to become a standard treatment, researchers must convince their peers of its merits.

A key question in setting up any research study is who will benefit from it? Therapeutic research is intended to benefit the subject, or patient, directly. Nontherapeutic research does not benefit the individual subject, but aims to contribute to medical knowledge and may benefit others in the future.³⁵ Whether the development of innovative treatment should be categorized as research or an extension of usual practice is debated. On the one hand, if the digression is small and focussed on the individual patient's situation then it may be justifiable and the innovation may be seen as a useful byproduct of effectively treating an individual patient. On the other hand, such innovation may be seen as 'trial and error' which is ethically and scientifically unacceptable and puts patients at risk because the procedures are not monitored or scrutinized sufficiently or at all.^{35, 36}

The process of setting up a medical research study involves obtaining ethical approval from the local research

ethics committee (LREC). They were introduced to help weigh up the potential benefits and risks of research for individuals and society. LRECs examine the scientific quality of the protocol, whether the investigators are competent and facilities adequate, possible hazards, measures for providing information and seeking consent, adequate compensation arrangements regarding harm from the trial, methods of recruitment, payment to investigators, and storage and use of subject-identifiable information.³⁵ For multicentre trials, multicentre regional ethics committee (MRECs) have been instituted both to speed the process of ethical assessment and to prevent duplication.

According to the BMA,¹⁷ although there is no legal requirement for researchers to obtain ethical approval for a study, it is almost impossible to get funding and becoming increasingly difficult to publish results without it. These committees examine the nature, purpose and process of proposed studies with consent processes being the subject of particular scrutiny.

Consent to participate in research must be valid and freely given. According to the Declaration of Helsinki (1964), subjects must be 'adequately informed of the aims, methods, anticipated benefits and potential hazards of the study and the discomfort it may entail'. Participants need information about the positives and negatives of any study and the alternatives before being able to give valid consent.

For minors and children, the same guidelines apply to consenting to take part in research as for treatment. Parental consent should be sought if the child is under 18 years, but it should not override refusal by a competent child. In UK law, parents cannot give consent for a child for procedures which are of no particular benefit and may carry a risk of harm, or refuse treatment which would be in the child's best interests, e.g. a life-saving blood transfusion.^{37, 38} Great care is taken in research on vulnerable groups, such as psychiatric patients.

Voluntariness is a key element in consenting to research. Subjects must not be pressurized in any way to take part and they must be free to refuse before or at any time during a study without this impacting on their basic care and treatment. This can be difficult, as doctors are in a position of power and may pressurize subjects unintentionally. Subjects may feel guilty if they refuse to participate or fear that a refusal will negatively affect their care. To avoid this situation, recruitment of subjects should be undertaken by someone other than the person carrying out the research, e.g. a research nurse who explains the options.³⁶ It should be made clear to subjects that a refusal will not be counted against them by their doctor. Written information for subjects and their GPs is particularly important.

Randomized control trials (RCT) are viewed by many as the gold standard for medical research, but are criticized by others.³⁶ This method randomly allocates participants into different groups who then receive

different treatments. It enables researchers to compare different interventions and determine which one produces the most beneficial results. If they are double-blinded, then neither the participant nor researcher knows which subjects are given the different interventions. This approach attempts to remove bias from the research. Yet, it also removes choice regarding treatment options from the participant and raises ethical concerns.

The use of placebos in research has come under scrutiny as it denies some subjects the potential benefits of the intervention. It is no longer considered ethical to use placebos if there are known treatments which may offer some benefit to the subject.³⁹ Whether or not placebos should be used to test the effectiveness of an existing treatment, where no other exists, is still debated.⁴⁰

Research also raises ethical concerns about confidentiality and the handling of medical records and information. To undertake a study, participants' medical records may become available to a number of people other than the doctor, research team or practice. The means of protecting confidentiality both during the course of the study and future use of the findings must be addressed. The BMA¹⁷ states that whenever patient-identifiable information is used, a medically qualified person should be identified to ensure the information is handled correctly and confidentiality is protected.

A vital part of good research is that it offers some benefit to the individual or society, that consent is freely given on the basis of detailed information, that confidentiality of patient-identifiable information is protected and that the research constitutes good science which is ethically sound.

To improve treatments, develop new techniques and interventions, medicine must rigorously assess current practice. This should not be at the expense of subjects' health, life or conditions or without careful consideration of the risks and benefits and ethical issues involved. These should be clearly explained to participants and they should be given the option to consent or refuse to participate.

Whether and how much money should be given towards research raises ethical questions of resource allocation.

RESOURCE ALLOCATION

Regardless of the specialty or setting (National Health Service (NHS) or private sector), the issue of limited resources is a reality for doctors. They face multiple pressures from patients, relatives, colleagues, management and Departments of Health, and doctors must make choices about how they spend their time, energy and money.

Levels of allocation

Resource allocation happens on different levels. In macro-allocation, central government divides its resources between areas such as health care, education and defence. Monies given to health care are then allocated between different hospitals trusts, primary care trusts and regional health authorities that distribute among primary, secondary and tertiary care. Micro-allocation includes decisions about treatment options, staffing levels and how much each service or department spends on research and administration.

NEEDS

For doctors on the front line, there is a **tension between** meeting the needs of individual patients and **assessing** the cost to the wider community. **Assessing** patient need is a key part of determining treatment options. Who defines needs and how are they defined? Abraham Maslow argued that there is a hierarchy of humans **needs**, ranging from physiological and safety needs to **self-actualization** (the ability to fulfil oneself and realize one's full potential). He also claimed that people seek to have lower level needs met first before focussing on higher level needs.⁴¹ Basic needs are those things universally required by all people to survive, such as food, water and shelter. Nonbasic needs are not required for survival, but contribute to our psychological, social and spiritual well-being.⁴² Within the context of limited resources, doctors may have to focus on the most urgent and pressing basic needs before addressing other needs.

PREFERENCES, DESIRES AND WANTS

Patients have a wide variety of health needs, but they also have desires and preferences about their treatment options. With the move away from paternalism, patients are less willing to do what the doctor tells them without question. Patients can and do communicate what they want and may also place demands on doctors for particular treatments or drugs; for example, parents who insist their child be given grommets for their ears. Of course, **sometimes patients want** things they do not need, such as **cosmetic surgery**, and need things they do not want, such as chemotherapy. There is a danger that doctors give in to pressure from patients and the most demanding patients get what they want, while others do not.

RIGHTS CLAIMS

Sometimes patient demands are based on 'rights'. Claims to rights have become a common part of modern Western culture. In medicine, the Patient's Charter and the

Human Rights Act (1998) have raised the notion of rights and correlative expectations in the public consciousness. When confronted with rights claims, doctors need to decipher what kind of rights are involved and whether or not they have a duty to fulfil them.

Legal rights provide a minimum standard of protection from harm for all people in a society. If anyone breaches another person's legal rights, then he/she can be taken to court and prosecuted. In medicine, if a doctor is negligent and harms a patient then he/she may be struck off or even sent to prison. Doctors and patients have clear duties to uphold and respect legal rights.

In contrast, the duties and responsibilities doctors have in relation to human rights are less clear. The Human Rights Act (1998) includes both the 'right to life' (Article 2) and a right to be free from 'inhuman or degrading treatment' (Article 3). These may conflict in medicine, particularly when considering issues such as 'do not attempt resuscitation' orders or whether or not to switch off the ventilator for an unconscious patient in the intensive therapy unit (ITU). How doctors are to make decisions in light of human rights, particularly when they conflict, is not clear.

ENTITLEMENTS

Arguably, a more useful means of **approaching** rights, expectations and duties is to focus on **entitlements**. To what are patients entitled in health care? In the UK, people are entitled to access the NHS and receive good quality care and appropriate treatment. Patients are not necessarily entitled to any and every treatment they want or demand. Doctors have a responsibility to provide care, but should only supply treatment which is likely to be successful, unlikely to cause harm and there are sufficient resources.

Doctors should be clear about the extent of their duties and recognize that these may vary depending on the type of rights involved. Patients also have responsibilities which include giving their doctor all information relevant to their condition and wherever possible not needlessly endangering their own health.

Patients do pressurize doctors based on needs, desires and rights and doctors must make decisions about how best to allocate their resources. These factors should be weighted **against** considerations of justice.

CONSIDERATIONS OF JUSTICE

One key moral basis for making and assessing allocation decisions is that of justice. Justice as fairness, equality and equity all have an impact on medical and health care. Fairness requires that a universal and uniform standard of treatment is provided for all.⁴³ It requires consistency in the way people are treated. To be fair, two patients with the same condition should have access to the same types

of services and care and be given the same treatment options.

Equality, like fairness, provides a minimum standard of consistency in treating people. It requires that similar cases are treated in similar ways and dissimilar cases are treated in dissimilar ways. Equality seeks to eliminate discrimination based on inappropriate grounds such as race or religious belief. Inequality exists where similar cases are treated in different ways. When allocating resources, doctors should be consistent in their dealings with patients and not allow discrimination based on clinically irrelevant factors to determine those decisions.

Although equality and fairness highlight important principles of justice and offer protection for individuals because of their focus on uniform treatment, they do not necessarily allow for differences in individual cases to be weighed sufficiently. In contrast, equity allows for differences in treatment between individuals, but these are permitted only for morally justifiable reasons.⁴⁴ It recognizes that giving people equal consideration is not the same as identical treatment.⁴⁵ A diversion from the normal standard of fairness and equality must be both justified and justifiable. Inequity exists where differences in treatment are not morally justified. If two patients have the same congenital abnormality of the ear and one is offered surgery and the other is not based on their economic class this would not be justifiable. Doctors must be able to provide a clear rationale for their decisions to the patient, relatives, other colleagues, management, government and wider public. The process and basis for these decisions should be communicated to the patient at the time and recorded in the notes.

When weighing up how best to use resources, doctors have to balance the needs, wants, rights and entitlements of the individual patient with their own duties and responsibilities to that individual and the wider community. This involves considerations of justice as fairness, equality and equity.

CONCLUSIONS

Doctors experience increasing pressure on their time, skills and resources. Daily, they are faced with difficult decisions, whether in relation to consent, confidentiality or withholding and withdrawing treatment. The moral basis on which they weigh up and make such decisions is crucial to their own practice and the delivery of patient care.

In our pluralist society, it may not be clear how and on what basis such decisions are made. Disagreements between doctors and patients, relatives and other colleagues can and do arise when confronted with moral choices and decisions. Reflecting on the specific ethical grounds for such decisions provides a more consistent framework for approaching such decisions. Whether they

involve principles, consequences, virtue theory or a combination of these, ethical frameworks must be applied in practice. How they are applied may be seen in light of the doctor's duty to care for his/her patients and protecting patients' best interests, which involves non-maleficence, beneficence, being just and respecting autonomy. All of these must be weighed and prioritized in the context of the doctor–patient relationship where both parties bring particular knowledge and skills to the decision.

When this relationship breaks down and some consensus about a moral dilemma cannot be reached, there is an increasing tendency to retreat to law to sort it out. This leads to polarization of the parties involved and defensive medicine as doctors seek to protect themselves rather than put the best interests of the patient first. The law can be a blunt instrument, serves as a minimum standard and addresses legal, not ethical, questions.

As one way to avoid this retreat to law and in order to resist practising defensively, doctors should be increasing their moral awareness. Addressing ethical dilemmas within medical practice and discussing them with patients and relatives is one means of avoiding ending up in the courts. Doctors should be able to justify their decisions ethically and be clear about the moral basis on which they were made. Such justifications may have to be given to patients, families, colleagues, management, the government and wider society. With increasing pressure from the media, it is important that doctors offer a moral, as well as clinical, justification for their decisions.

As medical science and technology continue to advance, ethical challenges will continue to be faced within medicine. Encouraging healthy debate and dialogue within the medical profession and good communication with patients, relatives and colleagues can help avoid defensive practice and legal battles. Doctors should be encouraged to reflect on the moral basis for their decisions, while being aware of the different moral perspectives and values of patient and relatives, and look for some common ground and shared values in the midst of disagreement rather than focussing solely on the differences.

KEY POINTS

- Medical ethics is necessary as part of good clinical practice in dealing with patients, families, colleagues and institutions.
- The doctor–patient relationship is characterized by partnership and good communication.
- The good doctor fulfils the duty of care, acting in the best interests of patients,

respecting their autonomy and acting justly.

- Good medical moral decision-making draws on principles, consequences and medical virtues.
- Consent and refusal of treatment are based on competence, the giving of full information, understanding of its significance and freedom of choice.
- Confidentiality is both legally and morally required, except in extreme circumstances.
- Withdrawing and withholding treatment is both clinically and morally permissible in situations of futility and in the best interests of the patient.
- Careful allocation of limited resources means clear setting of priorities and acting fairly, equitably and equally.
- The conduct of research is subject to strict ethical guidelines to safeguard the patient/participant and the researcher.

Best clinical practice

- ✓ In all dealings with patients, families and colleagues, doctors should recognize the need for high moral standards.
- ✓ Doctors and patients should both act in partnership.
- ✓ The patient's autonomy should be respected, while recognizing autonomy has limits.
- ✓ Good communication with colleagues and patients is vital.
- ✓ Doctors should not only do no harm, do good, act justly and maximize autonomy, but also have a duty of care and to act in the best interests of patients.
- ✓ Doctors should be able to recognize the need for and make moral decisions on the basis of principles, consequences and medical virtues.
- ✓ Consent and refusal are part of a process based on competence, full information, understanding of its significance and free choice.
- ✓ Confidentiality must be respected, unless legally required to be broken.
- ✓ Withholding and withdrawing treatment may be appropriate when the situation is futile and it is in the best interests of the patient.
- ✓ Resources should be allocated fairly and equitably.
- ✓ Research should be conducted ethically with good clinical and statistical grounds, consent, protection of confidentiality and communication.

INTRODUCTION

When these authors were first appointed as consultant otolaryngologists, the closest contact with the legal process that they envisaged was the writing of expert witness reports in personal injury cases. Along with this was a realization that there was a small chance that these reports might lead to a court appearance as an expert witness. The regional health authorities and later hospital trusts had by then been forced to accept vicarious liability for the actions of the consultants they employed so the only other contact that apparently was possible was the result of a claim alleging negligence in private practice. Although this event was feared by most consultants, the chances of a successful claim were and still remain low. The last decade and a half has seen some changes in how claims of clinical negligence are decided but the developments in other fields such as consent, confidentiality and clinical performance have been much more significant. The medical profession in general has twice been put in the spotlight by very major events which were subject to intense media interest: the Bristol Royal Infirmary Inquiry into unacceptable complication rates in the paediatric cardiac surgery unit and the trial of Harold Shipman who was convicted of murdering an unknown number of his patients have changed the way that the public views the medical profession. The response from politicians has been to try to tighten the legal framework in which doctors practise so that the public can be reassured that it can never happen again.

The law in England differs slightly from that in Scotland and Northern Ireland but most of the principles are the same. The first major subdivision is into criminal law and civil law. In criminal law, the state prosecutes an individual or an organization (the defendant) alleging breach of a law or statute. If the case is proven, the individual or organization is subject to a sentence, often a fine or a custodial term of some kind. In civil law, one individual or organization (now known as the claimant, formerly the plaintiff) brings a suit for damages against a defendant and seeks damages from that defendant. Ideally, the damages would exactly redress the loss suffered by the claimant. For instance, a claimant proved to have been swindled out of his car by a defendant might be happy merely to have his car back. In medical negligence cases, it is manifestly impossible to restore negligently caused losses so the damages are monetary. There are three important forms of monetary damages in clinical negligence: general, special and punitive or exemplary.

General damages are those awarded to compensate the successful claimant for pain and suffering. Special damages are those awarded to take account of loss of income, special nursing needs, etc., arising from the negligence. Punitive damages are exactly what they say they are: damages awarded to the claimant to punish the negligent defendant. These are similar in a way to a fine in criminal cases but are not awarded in clinical negligence cases in the UK where most defendants have insurance to cover any damages awarded against them.

Civil and criminal jurisdictions differ in two other important ways: in the standard of proof required and in the influence of statutes. In criminal cases, the standard of proof is 'beyond reasonable doubt' which is often taken to imply a probability of guilt of at least 95 percent. In civil cases the standard of proof is 'on the balance of probabilities' which means greater than 50 percent probability. This figure leads to some apparently illogical conclusions in the field of causation where it has been argued that, as far as the law is concerned, a 5 percent five-year survival is identical to a 49 percent five-year survival (so no compensation should be paid even if negligence is proven) but completely different from 51 percent five-year survival. The view of the House of Lords, the highest legal authority in England and Wales, on this subject is awaited.

The source of the criminal law is founded in the common law and on statutes passed by Parliament and, more recently, European law. Statutes, precedent and European legislation state what actions constitute criminal behaviour. In the course of a criminal trial, counsel may well cite a precedent of what has been said and what decisions were made by courts in the past in similar cases. In a civil trial, there may be no statute that has any relevance to the questions to be decided so the decisions are based almost entirely on what happened in previous cases. This is referred to as the common law. The common law is in a state of continuous development as civil cases are tried by high courts, such as the Court of Appeal and the House of Lords, which can introduce subtle changes in decisions that then become the common law. Much argument may then occur as to what exactly their Lordships meant. Was what they said in a previous case relevant to the one currently being tried? Even more debatable is whether or not the important remark was part of a judgement or some sort of subjunctive aside to the judgement in the form of 'if this case had been similar to case A then I would have decided as follows'. The next section of the chapter (see under Causation below) illustrates exactly how one word in a judgement can be important when the case referred to as *Bolitho*¹ is considered.

Besides major sections devoted to clinical negligence and the duties of an expert medical witness, this chapter examines the two most common questions asked of a medical indemnity organization's helpline: consent and the doctor's duty of confidentiality. The criminal law and the role of the coroner as they are likely to apply to surgeons in their professional activities are discussed. The duties of a consultant surgeon as a doctor and the mechanisms that are or shortly will be in place to ensure that these are complied with are described and the additional duties of that consultant as a trainer is also mentioned.

TORT

Before discussing clinical negligence and consent issues, it is relevant to review the legal principle on which these are

largely based. This is the law of tort or wrong done by one party to another. The two forms of tort that are relevant to surgeons are negligence and assault and battery.

There are four essential elements of the legal tort of negligence:

1. there must be a duty of care;
2. there must be a breach of that duty;
3. harm must have occurred;
4. the breach must have caused the harm.

Negligence occurs when party A is considered to owe a duty of care to party B, to have breached that duty and, as a result, harm has come to B. It must be shown that A could reasonably have foreseen that the breach might cause the harm. For instance, a driver travelling quickly on a country road should have it in mind that there might be a cyclist just around the corner. A second important aspect of negligence on which many clinical negligence cases fail is causation. This works on the so-called 'but for' test. It must be proved that, 'but for' the breach of duty by the defendant, the damage suffered by the claimant would not have occurred.

It is perhaps a surprise to many people that assault and battery are sources of both civil and criminal litigation. Assault is the threat of physical violence and battery is any unlawful touching or physical contact of one person by another. The law makes an exception for ordinary day-to-day contact such as occurs in a bus queue or when handing over change for a newspaper but this does not apply to medical examination. Only with consent (which will be discussed further under Consent below) does a medical examination become lawful. Without consent, approaching a patient with a shining Lack's tongue depressor at the ready is an assault and using it to depress the tongue is a battery. Although the act of opening the mouth probably implies consent, the patient has the option of lodging a civil claim alleging battery or even of reporting a possible criminal battery to the police. It is important to note that civil actions for battery, unlike those for negligence, do not require that there has been any harm. Patients seeking damages for lack of adequate consent can sue either in negligence (where the 'but for' test applies but consent must be truly informed) or in battery (where causation is not an issue but a much less rigorous consent is enough to refute the allegations).

NEGLIGENCE

Standard of skill and care

In deciding negligence the claimant must establish four things.

1. A duty of care was owed to the claimant.
2. There has been a breach of that duty.

age has occurred to the claimant.
The breach must have caused the damage.

To establish a duty it is necessary for a doctor/patient relationship to be in existence. There is no Good Samaritan law in the UK, and doctors only have a legal responsibility to people they have agreed to treat. In general practice the agreement arises by virtue of accepting a patient onto one's list. In a hospital setting, the agreement either arises out of the doctor's Terms and Conditions of Employment, or with private patients, as a result of contract.

Patients tend to be seen by several different doctors and, therefore, the question: 'who owes the duty of care?' may be a pertinent one. In the National Health Service (NHS), the employing authority will usually be named as first defendant as it would be liable to pay damages arising from any successful action by virtue of the principle of vicarious liability. Individual doctors may then be named as subsequent defendants.

An unresolved issue is who should be sued if a patient is placed on a waiting list, but suffers additional damage in the time it takes to receive a first appointment? Is the defendant the referring GP, or the Authority, or NHS Trust at whose clinic the patient is awaiting an appointment?

The standard of care is that of the reasonably skilled and experienced doctor. The appropriate test, known as the Bolam (*Bolam v. Friern Hospital Management Committee*) test,² states that it is:

the standard of the ordinary skilled man exercising and professing to have that special skill. A man need not possess the highest expert skill; it is well-established law that it is sufficient if he exercises the ordinary skill of an ordinary competent man exercising that particular art.

The standard of care relates to the specialty in which the doctor practices. A GP will not be required to possess the skills of a specialist. An inexperienced doctor cannot rely on his lack of experience as a defence to alleged negligence (*Wilsher v. Essex Area Health Authority*).³ However, a junior doctor may discharge his duty by seeking the help of a superior.

While a doctor is under a duty to keep himself appraised of developments in his area, this is subject to the bounds of reasonableness. Failure to read one article, which might have prevented the negligent act, could be excusable, while failure to be aware of new techniques that have become widespread may be inexcusable (*Crawford v. Board of Governors of the Charing Cross Hospital*).⁴

A doctor will not be negligent simply because he acted in a way that another doctor would not have done. The Bolam test establishes that a man is not negligent if he is acting in accordance with a practice merely because there is a body of medical opinion which would take a contrary view, provided there is a reasonable body of opinion

which supports the practice. A body of opinion must consist of at least two people. This statement has recently been qualified by the case referred to as Bolitho (*Bolitho v. City and Hackney Health Authority*).¹

Causation

In Bolitho, a registrar in paediatrics was accepted to be in breach of her duty of care by failing to visit an infant with breathing difficulties. Her defence was that, given the clinical circumstances at the time she should have visited, she would not have intubated the infant. The Court of Appeal had found that the failure to attend the infant constituted negligence. The House of Lords heard opposite expert opinions, one asserting that there was a body of opinion that would undoubtedly have intubated in those circumstances and the other that there was also a responsible body of opinion that would not have intubated. Their Lordships then reversed the judgement saying that the defendant's assertion that she would not have intubated, a practice supported by a reasonable body of opinion, meant that on the balance of probabilities the brain damage would have occurred even if the registrar had visited. The causal link from the failure to discharge her duty of care by visiting the patient to the harm suffered was therefore broken so no negligence could be proved.

Bolitho is important because it clearly brings Bolam into the field of causation and also because of the dissenting judgement of Lord Browne-Wilkinson. Referring to the reasonable body of medical opinion that would allow a Bolam-based defence, he said 'The use of these adjectives – responsible, reasonable and respectable – all show that the court has to be satisfied that the exponents of the body of opinion relied on can demonstrate that such opinion has a **logical** basis' (our emphasis). Later in judgement he qualified this by saying, 'it will very seldom be right for a judge to reach the conclusion that views genuinely held by a competent medical expert are unreasonable'. It is not yet clear how these comments will be used as precedents for future cases but they certainly will be. An example might be the practice of stripping all the mucosa from a vocal cord in Reinke's oedema. There is certainly a body of expert opinion that would condone the practice but, in view of our knowledge of the physiology of the superficial lamina propria, is it logical to operate in this way and can that body of expert opinion be considered responsible?

Proof of medical negligence

The onus lies upon the claimant to prove that the surgeon's negligent treatment caused the injury. It is not sufficient simply to prove that the surgeon's actions were reprehensible or even reckless if the claimant cannot go

on to show that their injury is directly attributable to the surgeon's poor performance. Hence, while it was clear that a casualty officer was in breach of his duty of care when he failed to examine a patient attending his department with the obvious signs of poisoning, there was a complete defence (*Barnett v. Chelsea & Kensington Hospital*)⁵ when it was shown that there was no antidote to the poison taken by the patient. This is similar to the reasoning in *Bolitho* above, although that case was much more complicated than *Barnett*. In *Barnett*, it was a straightforward and uncontested statement that the workmen who had accidentally ingested arsenic in their tea were doomed whether or not they received medical attention. In *Bolitho* the courts had to decide whether or not, on balance of probabilities, the hypoxic brain damage would have occurred even if the registrar had visited the child.

The standard to which the claimant must prove his case is on the balance of probabilities. This means that the claimant must show that his version of events and expert analysis are more likely to be true than those put forward by the defence. If the case for each side is evenly balanced then the claimant will fail. Hence, where a patient suffers a nerve palsy that could equally have been due to negligence, or could have occurred as an inherent risk of the operation even when performed with proper skill and care, the claimant's case will fail in the absence of some item of evidence to tip the scales in favour of negligence (*Ashcroft v. Mersey Regional Health Authority*).⁶

An apparent reversal of the burden of proof can occur where the likelihood of negligence is so obvious that it 'speaks for itself' (*res ipse loquitur*). In other words, a defendant may find that he is obliged at least to provide an explanation of the patient's injury that is consistent with reasonable care having been taken, even where the claimant has no positive evidence of negligence, where:

- there is no evidence as to how or why the accident occurred;
- the accident is such that it would not occur without negligence;
- the defendant is proved to have been in control of the situation in which the accident occurred.⁷

The doctrine first evolved in simple personal injury cases concerning falling objects (*Scott v. London & St Katherine's Docks*,⁸ *Byrne v. Boadle*⁹ and *Pope v. St Helen's Theatre*¹⁰), but has obvious attractions to a claimant in a medical case, where there may well be very real uncertainty as to how an injury came about, and where the often unconscious patient is entirely under the control of the medical team. Despite the fact that it is often pleaded, in England the doctrine has more often been conceded than litigated in medical cases, and so its ambit is unclear.¹¹ In practice the courts are reluctant to apply a doctrine derived from the relatively simple 'bumps and

thumps' of stevedoring to the complex issues of causation found in medical litigation. It has been said:

The human body is not a container filled with a material whose performance can be predictably charted.... because of this medical science has not yet reached the stage where the law ought to presume that a patient must come out of an operation as well or better than when he went into it.¹²

(*Girard v. Royal Columbian Hospital*)

Thus, as a matter of law, the onus of proving negligence will almost always fall on the claimant, although in cases where there is a strong and obvious inference of negligence from the very facts themselves (e.g. a retained swab (*Mahon v. Osborne*)¹³ or where the claimant woke from his anaesthetic with the septic finger still attached and an adjacent one in the bucket¹⁴) the defence may well find that onus discharged unless they are able to provide some alternative theory, not involving negligence, to answer the claimant's case.

Damages

A claimant having established negligence, and having proved injury as a consequence, the question turns to the assessment of the compensation to be paid. The court must award a sum of money that will, as nearly as possible, put the injured person in the same position as he would have been had he not been injured (*Livingstone v. Rawyards Coal Company*).¹⁵ In some jurisdictions (notably the USA) an element of punitive damages may be awarded. Such an approach has been rejected in England and Wales (*Kralj v. McGrath*)¹⁶ and the rest of the UK for mere inadvertent negligence. The argument is based on *mens rea* being present before the claimant can be given a monetary award by way of punishing the defendant.

Damages are broadly classified into two categories.

GENERAL DAMAGES

These include damages for pain, suffering and loss of amenity. This is the aspect of the claimant's loss which is not ascertainable by a mathematical calculation of economic loss and, in the past, was determined by a jury (*Ward v. James*).¹⁷ Juries were effectively abolished in personal injury trials in the mid-1960s. While the level of general damages will depend on the claimant's circumstances, and the suffering which the particular injury has caused the individual, a general bracket for a particular injury will be determined with reference to awards (adjusted for inflation) from previously decided cases. Obviously, it is impossible to 'compensate' someone for loss of a limb or for a life of continual pain so the awards are essentially conventional figures. As a guide, the

current conventional figure for injuries of the utmost severity is between £120,000 and £150,000, and so injuries of lesser significance will be a proportion of that 'maximum'. In a recent case in Teeside (*Levitt v. Hartlepool Area Health Authority*),¹⁸ a minor born deaf was awarded £50,000 general damages (adjusting for inflation in 2003 this would probably be £60,000), which included her total hearing loss.

SPECIAL DAMAGES

These are the specific 'out-of-pocket' monetary expenses and losses which the claimant has incurred up until the date of the trial. These will include loss of earnings, medical expenses, travel costs and the cost of any special equipment consequent upon the injury. Often there will be a claim for losses expected in the future. (Future loss is technically an item of general damages as its assessment is uncertain and it was formerly a matter for the jury to determine. As a matter of practice, the calculation of future loss is inseparable from that of past loss, many of the same arguments rehearsed in both, and one flows naturally to the other.) The amount of money at issue will depend almost exclusively on the particular circumstances of the claimant (*Lim v. Camden Health Authority*),¹⁹ guided by the principle that a claimant should only recover what he has lost as a result of the injury. He must prove that his expenditure was (or will be) reasonably necessary, and that his needs cannot be met more cheaply by other reasonable means.

As a rule, English law seeks to compensate a claimant by way of a single lump sum award. This creates obvious problems where a claimant is likely to remain unemployed or requires continuing care for many years in the future. The only certain result is that the claimant will be either under- or overcompensated, depending on how circumstances unfold. This problem has not been solved, but ameliorated in certain cases. Where a claimant suffers a condition that may deteriorate significantly in the future, rather than receive a small sum to represent the risk, they can apply for an order for 'Provisional Damages', which leaves it open to the claimant to come back to court at a later date.²⁰

In very large claims where the claimant's life expectancy will determine the level of the award, the risk can be borne by an insurance company by the purchase of an annuity. This is known as a 'Structured Settlement'.

Dealing with medical negligence claims

What happens when a surgeon is sued?²¹ The Civil Procedure Rules 1998²² are considered below. They require that, in cases of clinical disputes, a pre-action protocol be followed. This sets procedures and time limits for various stages of the process of being sued. There are

also recommendations for Trusts about how they should respond to a claim and what processes should be in place to ensure that they are able to respond in an appropriate and timely way. In effect, the pre-action protocol will penalize a Trust which has such a poor clinical governance structure that it is unable to respond to a claim in a relatively short time.

What the individual consultant surgeon will experience if his patient sues him alleging negligence will differ in some ways depending whether the patient was a private patient or an NHS patient. The first stage of the proceedings is the same: the patient, having found some means of financial support for his or her claim against the health care provider (a matter outside the remit of this chapter but considerably more difficult than formerly) will request, via a solicitor, release of notes. In private practice, the consultant will need to release these notes himself and is wise to check with his anaesthetist, the private hospital and other doctors involved in the secondary care that they will do the same. The consultant would be most unwise at this stage if he did not inform his medical indemnity organization and seek their help and advice. If the case is an NHS one, the matter must be referred to the Trust's legal department immediately. If the clinical governance system in the Trust is working well, there is a good chance that the events have already been reported to the legal section via an incident form and that contemporaneous statements have already been taken and filed in preparation for a potential claim. Alternatively, the claimant may have already used the NHS complaints' procedure so all the statements from that will be available. A Trust is vicariously liable for the actions of its employees and so the legal department should take over all further responses to solicitors and communication with the defendant legal team. Both Trusts and independent practitioners have 40 days to provide the copy medical records and failure to meet this deadline will prejudice any defence.

The potential claimant's solicitors will now obtain an expert report on the medical records with examination of their client if appropriate and can decide whether or not the claim has merit. If it has, they will serve a letter of claim on the health care provider setting out a summary of facts, the main allegations of negligence, description of injuries and an outline of losses. This may include an offer to settle. The defendant organization or individual must provide a reasoned answer within three months of receipt.

In addition, the defendant's solicitors will be concerned to obtain guidance from experts swiftly and, once received, be able to form an initial view about whether or not the claim is defensible. The assessment of a claim at this stage will be facilitated by recent rule changes which have been made concerning the conduct of personal injury actions, including medical negligence litigation. These changes require that at the time of service of a writ, a claimant must also submit a medical report setting out

the claimant's condition and prognosis, together with a Schedule of Special Damages said to result from any alleged negligence. Traditionally, such information was not available until much later in the litigation process. The change has resulted in a defendant's solicitors being able to assess the potential value of a claimant's claim at an early stage. Accordingly, following that initial expert opinion, a settlement can be proposed early in the proceedings on behalf of the otolaryngologist, if appropriate.

If settlement is desired but cannot be negotiated between the solicitors, then the solicitors acting for the otolaryngologist may try to settle the claim by what is known as a 'payment into court'. In making a payment into court, the defendant can make an assessment of the damages which might be awarded in due course at trial, if negligence is established. If the trial judge awards a sum higher than the level of the payment in, the claimant will receive his or her costs in the usual way. If, however, the sum awarded is the same or a lesser sum than, as a general rule, all costs of the action, including the defendant's costs after the payment into court, must be borne by the claimant. The claimant has 21 days to decide whether or not to accept the payment in. Thereafter the costs conservancies will operate. In cases where the claimant is legally aided, this device is of more limited assistance to a defendant. In other circumstances, there may well be a strong incentive to a claimant to accept a payment into court through fear of being prejudiced on costs in this way.

Following the service of a defence, in response to allegations contained in the statement of claim, both parties may raise requests for further information about their respective pleadings, and the claimant may choose to file a reply to the defence.

Directions concerning the conduct of a claim will be given by the court, usually after the pleadings are completed. In the High Court, a formal hearing will take place to consider these directions, but in personal injury actions brought in the County Court, a series of so-called automatic directions is given by the court. These are rarely, if ever, appropriate in medical negligence cases and it is therefore usual for the parties to apply to the court for specific directions to be given. These directions will provide for, among other things, the disclosure of witness statements as to fact and expert reports. In the past, in medical negligence actions, neither expert reports nor witness statements were disclosed by one party to another. Only at trial would the nature of the respective cases become clear. However, as a result of recent cases and changes in the procedural rules, expert reports and witness statements must now be disclosed, and this will be ordered by the court at a directions hearing. It is usual for witness statements to be disclosed, followed shortly thereafter by expert reports, in order that experts can consider this information available from the other side in preparing the report. The exchange of

both statements and reports gives a further opportunity for review of the case, both by claimant and medical defendant. At this stage the claimant may realize that the claim is weak and the case may be discontinued. Equally, the defence may feel that the case is not defensible and settlement negotiations or a payment into court may follow.

TRIAL AND PREPARATION FOR TRIAL

If the exchange of witness statements and expert reports does not promote the settlement of a claim, then the case proceeds towards trial. In medical negligence actions, a fixed date for trial will usually be given by the court because of the significant number of clinicians who may have to make themselves available, either as experts or as witnesses of fact.

By way of preparation for trial, both parties should arrange conferences with counsel in order to review the case in detail, and ensure all preparations are complete. If the defence considers that the case should be settled, or there are certain aspects of the case where a defendant may be vulnerable, a payment into court may be made. The payment in may be limited to those aspects of the claim where the defendant could be found liable. The claimant has 21 days within which to accept the payment in before the penalty of costs starts to run. As a significant proportion of the costs of an action result from the trial itself, the defendants are usually anxious to make any payment into court before 21 days in advance of the trial. Thereafter bundles of documents must be prepared for use in the court by all parties, which will include the pleadings, medical records, witness statements and expert reports.

A proportion of cases are settled literally at the doors of the court, the last opportunity for compromise before further significant costs of trial are incurred.

If no compromise can be reached, the trial will commence with an explanation of the case to the judge by counsel for the claimant, setting out the relevant events and the nature of the allegations. The claimant's counsel will then call witnesses of fact, usually followed then by expert witnesses. Each witness will be cross-examined in turn by the defence, and then re-examined by claimant's counsel if necessary. When the claimant's evidence has been called, the defence case is then put in the same way, and usually in the same order.

The trial judge may allow variation in this order of evidence, particularly in complex cases, so that witnesses for both sides are called first, to be followed then by experts. This will allow experts to hear all the evidence of fact before giving a final opinion. However, the present arrangements for disclosure of witness statements make such variation rare.

At the conclusion of the case, the judge will usually hear submissions from counsel on the law to be applied and the appropriate level of damages to be awarded if the

claimant is successful. It is usual then for the judge to reserve judgement, to be delivered at a later day, as most negligence cases are complex and will require some consideration. Once judgement is given, and if the claimant is successful, the judge will indicate the level of damages to be awarded. Only at that stage is the judge informed about any payment into court which may have been made, and the costs to be awarded can then be considered.

FUNDING OF NEGLIGENCE CLAIMS

Otolaryngologists may well have been concerned at the possibility that medical negligence actions in England and Wales will follow the pattern of the USA, and that the perceived increase in the number of actions here may continue. However, with the reduction in the eligibility for legal aid, many actions which would have been funded by legal aid in the past will now have to be funded privately. The introduction of contingency or conditional fees is unlikely to assist all those who are no longer eligible for legal aid. As an incentive for the claimant's solicitor, the conditional fee system²³ will allow the solicitor to claim twice the rate of fees they might have otherwise obtained in a successful action. There is a risk that the solicitor might receive no payment at all if the case is unsuccessful. As suggested above, solicitors acting for patients are therefore likely to take on fewer claims,²⁴ concentrating on those where liability is obvious and can be quickly established. The result is likely to be that there will be no significant increase in the number of medical negligence actions in the short term. Indeed, it is possible that there will be a reduction at the expense of patients who might otherwise have had successful claims for compensation.

CONSENT

Much medical litigation is caused by the practitioner's failure to disclose adequate information about the risks inherent in a given procedure. Common law recognizes the principle that every person has the right to have his bodily integrity respected. There is a presumption that a person should not be exposed to risk unless he has voluntarily accepted that risk, based on adequate information and adequate comprehension.

Obtaining consent to carry out an operation is necessary to avoid three sorts of legal jeopardy. The first and second arise because any touching of another person is a potential battery. (Assault is the threat of causing physical injury. An unconscious person can be battered but cannot be assaulted.) This means that, in very exceptional circumstances, a surgeon performing an operation without consent may be prosecuted in the criminal courts for alleged criminal battery. A more likely

outcome of such surgery is a civil case seeking damages for the tort (or wrong) of battery. There is no need to show that anything went wrong with the surgery, merely that it was carried out without valid consent. The third, and much the most likely legal outcome regarding consent, is that the claimant tries to show that he was not warned of the risks of a proposed therapy that resulted in harm and that, had he been warned of those risks, he would have refused the treatment. An example might be a patient with a dead ear after a competently performed stapedotomy who was not warned of that risk before surgery. He may well be able to claim damages from the surgeon because he can say that 'but for' the surgeon's failure to warn of the risk, he would not have undergone the surgery. It is immediately obvious that any careful surgeon must record what potential adverse outcomes of a proposed operation have been discussed with a patient. If it is not recorded in the notes, courts have become sceptical of a statement such as 'it is my usual practice to warn of these risks'.

The question of how much information must be given to the patient will vary from situation to situation, but is generally set by the professional standard according to the Bolam test, with doctors being arbiters of how much information should be given. This means that, in the example above, if the defendant surgeon could assemble a respectable body of opinion whose practice would not be to warn of the risk of dead ear, his conduct did not breach a duty of care. Notably, in England and Wales, there is no notion of informed consent, as in the USA, whereby the amount of information to be disclosed is dictated by what a patient would want to know.

This is modified to a degree by the case of *Sidaway* (*Sidaway v. Board of Governors of the Bethlem Royal Hospital*)²⁵ in which the House of Lords held that where the proposed treatment involved a substantial risk of grave or adverse consequences such that, notwithstanding any practice to the contrary, a patient's right to decide whether to consent to the treatment was so obvious that no prudent medical man could fail to warn of the risk (save in emergency or some other sound clinical reason for nondisclosure), then it would be negligent not to warn. To continue the example above, the claimant could argue that total deafness in one ear is such a disability that any reasonable patient would wish to be told about it preoperatively.

Accordingly, the right of the doctor (acting in accordance with a reasonable body of medical opinion) to decide what the individual patient should be told remains enshrined in English case law. Such medical paternalism, which may be in the best interest of some of our patients, is currently and repeatedly being questioned. The doctor should realise that in *Sidaway* when the question 'is informed consent a part of English law?' was put to the five law lords, the answer was not unanimous. Scarman said 'Yes', Diplock said 'No' and Bridge, Keith and Templeman said 'Yes with reservations'.

In assessing which material risks should be mentioned, doctors should consider the degree of probability of the risk materializing and seriousness of possible injury if it does. A risk, even if it is a mere possibility, should be disclosed if its occurrence would cause serious circumstances (*Hopp v. Lepp*).²⁶ Medical evidence will be necessary for the court to assess the degree of probability and the seriousness. A further medical factor upon which expert evidence will also be required is to assess the character of the risk, i.e. is this risk common to all surgery or is it specific to the particular operation? Special risks inherent in a recommended operation are more likely to be material.

The legal standard of disclosure required in response to direct questions is also set by the professional standard (*Blyth v. Bloomsbury Health Authority*).²⁷ Although the amount of information given must depend upon the circumstances, as a general proposition it is governed by the Bolam test (*supra*).

In Australia, the doctrine of informed consent has gone one stage further from *Sidaway* where the reasonable patient was considered the arbiter of what risks should or should not be disclosed preoperatively. In *Rogers v. Whittaker*,²⁸ it is clear that the risks that must be disclosed are those that affect that one patient and not the generality of reasonable patients. To take the stapedotomy analogy one last stage further, few surgeons would warn of a dead ear risk of 1 in 2000 operations and probably the reasonable patient would be unlikely to want to know that this was a complication as it is so unlikely. The question arises of whether the patient having that operation on an only hearing ear might view the risk differently and want to be aware of it in making a decision.

Who can give consent?

There are three categories of patient described in the Department of Health Reference Guide to Consent for Examination or Treatment: the adult with capacity to consent; the adult without capacity to consent; and children and young people.

CHILDREN

Section 8(1) of the Family Law Reform Act 1969 provides that a person over 16 may give a valid consent to medical treatment as though he was an adult. As regards children under 16, the general principle is that laid down in the *Gillick* (*Gillick v. West Norfolk and Wisbech Area Health Authority*) case,²⁹ that the parental right to determine whether or not a child under 16 should have medical treatment terminates when the child achieves a significant understanding and intelligence to enable him or her to understand fully what is proposed. Until such time, the

parents, or others acting in loco parentis, may give their consent or refusal to medical treatment. Recent case law suggests that it may still be possible to treat a seemingly competent child who is refusing to give consent, providing someone else with the capacity to consent provides consent on the child's behalf (*In re R*, and in *re W*).^{30, 31}

MENTALLY INCOMPETENT PATIENTS

Where a patient is unable to provide consent on his or her own behalf by reason of mental incapacity, no one else, including a court, may give consent on that person's behalf. The doctrine of necessity, however, permits a doctor to lawfully operate on or give other treatment to adult incompetent patients, provided that the treatment is in their best interest, either to save their lives or to ensure improvement in their physical or mental health (*Re F*).³²

JEHOVAH'S WITNESSES

Certain groups of patients, including Jehovah's Witnesses, may refuse to receive blood transfusions or other life-saving therapies. The Court of Appeal has affirmed patients' rights to refuse medical treatment, even if this will result in their death; nevertheless, for such a refusal to be effective, the court must be satisfied that at the time of refusal the patient's capacity is not diminished by illness or medication or given on the basis of false assumptions or misinformation. In the case of *Re T*,³³ Lord Donaldson said:

An adult patient who suffers from no mental incapacity has an absolute right to choose whether to consent to medical treatment, to refuse it or to choose one rather than another of the treatments being offered.

A decision to refuse medical treatment does not have to be sensible, obviously rational or well considered, and in the case of a competent patient, the doctor cannot override the patient's wishes because he believes it to be in the patient's best interests.

OTHER SPECIAL GROUPS

Pregnant women, patients who are human immunodeficiency virus positive or suffering from acquired immunodeficiency syndrome and the elderly do not represent special categories for the purposes of consent. Although the amount of information which has to be given to a patient varies from case to case, a decision to withhold information solely on paternalistic grounds that it may deter the patient from accepting the therapy may not be justified in law.

CONFIDENTIALITY

Doctors are well aware of their duty, originally stated in the Hippocratic oath, of confidentiality. What is often not appreciated is the common law and statutory basis of this duty and the circumstances in which confidential information may legally be revealed. There is a common law duty placed upon professionals to guard confidential information. A patient may sue a doctor through the civil courts if there is alleged to have been damage as a result of breach of confidentiality. The Data Protection Act (1997) places a statutory duty on anyone who holds patient identifiable data (in any form) to guard and release that information under strict controls. Any surgeon who keeps any sort of patient identifiable information at his residence (where his employer's blanket registration under the act will probably not apply) and who is not registered with the data commissioner breaches the provisions of the act. It is particularly important to note in this context that, if disclosure is properly requested, it is an offence to fail to disclose ALL of the records, both computerized and manual.

The second statute that obliges surgeons to care for information appropriately is the Human Rights Act (1998). This enshrines in UK law the sixth clause of the European Convention on Human Rights granting citizens an absolute right to privacy and to family life.

There are a number of instances in which confidential information can be released. The first is with the consent of the patient. This is sometimes implied consent such as applies when a GP releases confidential information in a referral to a consultant (and so to both secretaries). On other occasions, there needs to be expressed consent, for instance in release of information to insurers when a holiday must be cancelled. Sometimes a doctor is obliged to release information. The statutory examples concern the Terrorism Act 2000, the Abortion Act 1967 and the infectious diseases regulations. A court has power to require disclosure of records and there are several cases where disclosure is appropriate in the public interest. These are to protect the rights of others, such as reporting to prevent or detect serious crime or to prevent suspected child abuse and in reports to the Driver and Vehicle Licensing Authority. In all cases of this nature where the disclosure is not governed by the Data Protection Act, the information released must be no more than that necessary to comply with the public duty. A surgeon with any doubt as to how to resolve the conflict between duties of confidentiality and the public interest is well advised to consult his or her medical indemnity organization and to ensure that the final decision is one with which a responsible body of medical opinion would concur (Bolam).

The situation after the death of the patient is different. Doctors have a duty to disclose on death certificates and to national confidential enquiries as well as to the police and courts, especially the coroner. Data protection no longer applies and the relevant statute is the Access to Health

Records Act 1990. This clarifies that executors or, failing them, next of kin can consent to release of medical records. It appears that anyone with a legitimate claim to view the record can see that part of the record that is relevant.

THE CORONER

By the time this chapter is published, it is likely that the changes in the role of the coroner will be clearer. For some time, there has been unease about exactly what coroners are expected to do but the moves to reform have been hastened by the Shipman case and the subsequent inquiry.

Harold Shipman, a general practitioner, was found guilty of murdering a large number of his patients. For a number of successive years, the local coroner received considerably greater numbers of reported deaths of patients of Dr Shipman than of any other local GP. Despite this, no alarm bells appear to have rung and Dr Shipman's murderous activities continued unabated. The Shipman Inquiry which followed the criminal trial have recently been completed and they seem likely to make wide-ranging recommendations about the role of the coroner and the General Medical Council (GMC). There is also an independent inquiry into the office of coroner which may possibly arrive at a different conclusion.

As things stand at present, the coroner for a particular area is appointed by the Crown and is usually a lawyer. There are a few medical coroners but these are less prevalent than previously. The coroner has a number of duties of which the investigation of certain deaths is the one relevant to this chapter. In the course of these investigations, the coroner has wide powers to call or subpoena witnesses and to make whatever investigation he sees fit to establish the facts relevant to the death. The equivalent officer in Scotland, the Procurator Fiscal, has similar powers, which may be even wider.

When the coroner is mentioned, most doctors ask three questions: what deaths must be reported to the coroner; what verdicts can be brought and will these criticize the doctor; what must I do if required to write a report for or appear before the coroner?

The following deaths must be reported to the coroner:

- violent or unnatural death;
- death in custody (even if the prisoner was licensed on leave to attend the hospital);
- death where no doctor is able to issue a death certificate.

Most jurisdictions also have local agreements about the reporting of deaths within a certain period after hospital admission and after surgical procedures. Coroners usually wish to know about deaths from notifiable diseases, industrial diseases and those in receipt of war pensions.

The range of verdicts that the coroner can return is surprisingly limited. The coroner's court is (in theory at

least) not adversarial and no finger of blame should be pointed by the court. The coroner's remit is to establish the identity of the deceased, the time and place of death and the mode of death. Although death due to gross neglect is an acceptable verdict, death due to negligence is not. In practice, of course, the family of the deceased and their lawyers may use the proceedings of the coroner's court to assess whether or not an action in negligence is likely to succeed.

What about the surgeon called upon to provide a report to the coroner? The first piece of advice would be for the surgeon to contact his or her defence organization for support. The report itself should be factual and full and directed to a nonmedical audience. The report should not contain opinion but just facts. In particular, a report to a coroner should never contain the words 'negligent' or 'negligence'. Not only are these a matter of opinion and not fact, but they also have special well-defined meanings for lawyers that may not be apparent to doctors.

In most cases, the report will be all that the coroner needs and the doctor will not be required to appear. If the coroner feels that the evidence that the doctor can give may be crucial to his investigations, then he will summon the doctor to the inquest. Sometimes the family of the deceased will see this as their opportunity to confront the doctor who they see as the source of their grief. To be fair, sometimes the process works well, the family see that the doctor is not some kind of ogre and the resentment fades. Even if this does not occur, the coroner should ensure that the family do not persecute the doctor and that the proceedings remain directed towards establishing the who, when, where and how but not why the deceased perished.

If the doctor anticipates a difficult inquest, he may be accompanied by legal assistance but the solicitor may not answer for him nor is there any cross-examination of the other side. Defence organizations can advise the doctor but there is always a risk that the presence of a legal advisor will make the family (and the coroner) suspect that some sort of cover-up is being attempted.

Doctors summoned to the coroner's court need to follow the usual rules of court appearances – dress smartly but conservatively and do show appropriate respect to the coroner. Bring the notes or fair copies and copies of the reports already supplied and read them through before the case opens. Remember that the doctor is a witness and not an advocate or defendant and so there is no problem in asking for a question to be repeated or for a pause while the notes are consulted before answering.

THE ROLE OF THE EXPERT

An expert medical witness is instructed by either the defence or the claimant to give his or her opinion on the medical matters pertinent to the case to the court. This evidence is different from that of a material witness who is

asked for the facts. The expert's job is to interpret the facts for the court. In simple terms, it is 'to give impartial advice and opinion'. Many otolaryngologists will be called upon to give expert opinion on personal injury cases where neither the claimant nor the defendant is a clinician. The many reports on noise-induced hearing loss that have been written by otolaryngologists are a form of written expert testimony in just such personal injury cases. A few otolaryngologists will be asked to prepare reports that assist courts in deciding clinical negligence claims and the special circumstances that pertain to these are discussed below.

Until the Civil Procedure Rules 1998 came into force, experts were retained by either the claimant or defendant's side and to some extent this remains the case. In theory, an expert's report would be the same whether he was instructed by the solicitors of the claimant or those of the defendant. The 1998 Rules have made it clear that the duty of an expert, whether he is expecting to be paid by the defendant or by the claimant, is to produce for the court an unbiased opinion. The 1998 Rules encourage a court, where practical, to appoint a single joint expert to produce such an opinion. They also give direction about exchange of reports, communication between and with experts and the expert's right to ask the court for directions.

In practice, the expert's evidence is usually contained in a report and it is rare for an expert to have to appear in court. The form and content of an expert report were previously based upon a well-known civil case.

In the *Ikarian Reefer* (*National Justice Compania Naviera SA v. Prudential Assurance Company Ltd, The Ikarian Reefer*),³⁴ Mr Justice Cresswell stated that he considered that a misunderstanding on the part of some of the expert witnesses had taken place concerning their duties and responsibilities which had contributed to the length of the trial. Although this was a shipping case, the seven duties and responsibilities laid down have equal validity for medical experts.

1. Expert evidence presented to the court should be, and should be seen to be, the independent product of the expert uninfluenced as to form or content by the exigencies of litigation.
2. Independent assistance should be provided to the court by way of objective unbiased opinion regarding matters within the expertise of the expert witness. (An expert witness should never assume the role of advocate.)
3. Facts or assumptions upon which the opinion was based should be stated together with material facts which could detract from the concluded opinion.
4. An expert witness should make it clear when a question or issue fell outside his expertise.
5. If the opinion was not properly researched because it was considered that insufficient data was available then that had to be stated with an indication that the opinion was provisional. If the

witness could not assert that the report contained the truth, the whole truth and nothing but the truth, then that qualification should be stated on the report.

6. If after exchange of reports an expert witness changed his mind on a material matter then the change of view should be communicated to the other side through legal representatives without delay and when appropriate to the court.
7. Photographs, plans, survey reports and other documents referred to in the expert evidence had to be provided to the other side at the same time as exchange of reports.

More recently, the Civil Procedure Rules have modified these directions. The expert should obtain the Civil Procedure Rules Chapter 35 and read sections 1.1 through to 1.6, which is too extensive to reproduce here.

Before writing a report the expert should be aware of what the solicitor requires. Reports usually refer to one or more of the following six areas which are:

1. An initial statement on the possible merits of an allegation for a claimant before notes and other evidence are obtained.
2. Liability.
3. Causation.
4. Current condition.
5. Prognosis.
6. Expert opinion on an area of medicine.

A quote should be given on the cost of the report in advance. Lawyers may have no concept of the cost in time and research to answer what to them may be the most simple of questions. The solicitor will not be pleased to receive a report of 100 pages with detailed bibliography costing £2,000 when the damages sought are only £500 for a relatively minor event.

The report should be double spaced and typed on A4 paper. Each sheet should have the name of the claimant or defendant typed in the top right-hand corner and be separately numbered. It is also helpful to number the paragraphs. The names of the parties should be stated as should the requesting solicitor or insurance company. It is inadvisable to use the word 'negligent' in the report. Negligence may be implied by using phrases such as 'falling below an acceptable standard' or 'followed a course of action that could not be supported by any body of medical opinion'. Phrases such as 'reckless action' or 'flagrant disregard' may have a special meaning and lead to criminal charges rather than a civil case.

There is always the possibility that the credentials of the expert will be tested in court. It is extremely unwise for the expert to step outside his field. Should he be forced to comment outside his field of expertise he should add the rider that he is speaking only as an average medical practitioner. The expert will need to be au fait with up-to-date research in his own field.

The medical expert in clinical negligence

The medical expert retained in a case of medical negligence is usually asked to elucidate the areas of medical contention within a case. He needs to be aware of the various views on current practice even if these views are held by a minority of doctors, provided always that the minority is a reasonable one and that the practices supported are logical (Bolitho). Although the temptation is to be an arbitrator of medical colleagues, in court, this is the province of the judge. Nevertheless, the expert will be asked to comment as to whether the claimant's complaint has merit. When acting for the defence the expert will inevitably come across cases where defence is impossible. Here it is the expert's duty to advise that a speedy settlement be made to the aggrieved patient. This will have the secondary benefit of avoiding a colleague's professional shortcomings being exposed to public criticism in court. Rarely, some doctors expect their colleagues to defend them whatever the circumstances. Hence, being an expert can lead to criticism or alienation by colleagues.

Medical negligence cases can take an inordinate amount of time. Not only may the expert have to inspect all the records, examine the claimant and prepare reports, he will have to do research, attend meetings with solicitors and counsel and attend court. A single case may, in unusual circumstances, take up to 100 hours of time or more. The expert should never take on a case if he cannot afford the time.

Subsection 1.6 of the practice direction requires that experts comply with the relevant approved expert's protocol. As might be expected, there is a detailed pre-action protocol for the resolution of clinical disputes. Although this is aimed primarily at the legal profession, it is required reading for any doctors involved in providing expert testimony in clinical negligence cases. In particular, the times allowed by the court for the completion of various stages of the claim and the defence are clearly stated.

The doctor as an expert witness in court

The purpose of expert opinion given in court is to persuade the judge that one side of a case has greater merit than the other. It is the judge who will decide between the two sides of the argument. The expert should not be tempted to usurp the role of the judge for this may do untold damage to his own side or at the very least earn a rebuke which may undermine his confidence.

In court, the expert should wear conservative clothes. Evidence should be given in a straightforward, unequivocal manner. A personal view may be represented especially in response to a direct question but should always be tempered with information about acceptable

alternative practice and opinion. He should always be prepared to concede points if it is appropriate to do so, and not to adhere rigidly to one view when that cannot be sustained. The expert often has difficult concepts to convey to the judge. The expert should not hesitate to use pictures, models or even video to illustrate a point but should avoid being seen as a flamboyant 'show off' lest he discredits himself by not giving due respect to the court.

The usual course of examining a witness in court is that the barrister for the side calling the witness will examine that witness and try to anticipate and pre-empt difficult questions from the other side. Counsel for the opposing side will then cross-examine the witness and may attempt to undermine the evidence given by the expert or the standing of the expert in his profession. Above all, the expert must not see this as a personal insult lest he should lose his temper and hence his dignity. After this potentially hostile cross-examination, the first barrister is permitted to re-examine the witness and try, if necessary, to restore the faith of the judge in that witness.

PERFORMANCE AND COMPLAINTS

Besides using the legal system to sue a surgeon in tort, patients have recourse to a number of mechanisms to resolve concerns about how they have been treated or managed. Some of these mechanisms have the potential to involve doctors in disciplinary or performance investigations so the two elements are considered together. A patient or a family unhappy with the outcome of a surgical process can of course sue in the tort of negligence but this is expensive and will succeed in only a few cases. Another option is a complaint to the Trust employing the surgeon. Trusts are obliged to have a complaints procedure and the patient is entitled to a prompt reply from the chief executive. In practice, the time limits are so tight that especially when the complaint is a complex clinical one (rather than the more usual gripes about hospital food or parking for visitors) the first reply is a form letter. Following this the complaint should be answered point by point with an apology if appropriate. If this is rejected by the patient then the complaint is passed to a convenor (usually a nonexecutive director of the Trust) whose job is to decide whether or not to convene an interim review panel to try to resolve the matter. This should be done only if, in the convenor's view, there is no other way to resolve the complaint and there is a good chance that the panel will achieve such a resolution. The convenor also sets the terms of reference of this investigation. A glance at the advice to convenors on this suggests that this structure was neither well thought out nor transparently nonpartisan. Convenors who refuse to sanction further investigation are seen as agents of the Trust that they work for. Aggrieved patients tend to see the narrow terms of reference that may be

required to allow the review panel to function as further evidence of attempts to quash legitimate complaints. Some patients turn at this stage to clinical negligence proceedings; as soon as this happens, the complaints process ceases. The independent review panel will in time produce a report to the complainant, the complained against and the Trust chief executive. The chief executive must then report to the complainant what action has been taken. Among the possible actions are Trust disciplinary procedures or report of a doctor to the GMC. Before considering what threats the GMC poses to surgeons, the Health Service Commissioner must be mentioned. This officer, also referred to as the ombudsman, can review the decisions of the convenor not to set up an independent review. There may also be grounds for appeal to the ombudsman if there are problems with the terms of reference or the conduct of the independent review. Following general dissatisfaction with the process and especially the role of the convenor, there has been a process of consultation followed by a report on how the system might be improved. If the legislation goes through to put this report into practice, then the convenor will disappear and the follow-up to failed local resolution will be the Healthcare Commission.

If the investigation of a complaint leads to further investigation of the conduct or performance of a doctor, there are a number of forms that this can take. One is an internal investigation by the doctor's Trust. Although there are regulations that govern the conduct of such investigations, there is such a variety of approaches that this chapter cannot be dogmatic. It is clear that a Trust must not unjustifiably suspend a doctor pending investigation and then drag its heels in the investigation. There may well be a case against the trust under the Human Rights Act (1998) and the doctor is probably best advised to consult his or her defence organization.

Two new organizations may put a doctor's reputation or right to practise in jeopardy. These are National Patient Safety Agency (NPSA) including the National Clinical Assessment Authority (NCAA) and the Healthcare Commission. The Healthcare Commission arose out of Commission for Healthcare Audit and Inspection which arose from the Commission for Healthcare Improvement (CHI). The NCAA will deal with concerns about the performance of individual doctors by investigating problems and arranging performance assessments where necessary. Memoranda of understanding have been agreed between the NCAA and both CHI and the GMC so it is clear that a suggestion of deficient performance or conduct uncovered by one of the three organizations may well be reported to the other two.

The organization that these newer groups feed to and which has disciplinary control over doctors in the UK is the GMC. This organization has a statutory duty to maintain standards and ensure that doctors registered with the GMC do not endanger the public. The GMC is bedevilled by lots of committees with similar acronyms

but there are basically three routes through the system. The first stage is usually the reporting to the GMC by a Trust, by a member of the public, by another doctor or the NCAA.

Increasingly, the GMC is looking at reports in the media which suggest poor performance or conduct and initiating proceedings on the basis of these. The complaint is screened and the decision made to reject it at this stage or to refer it on for investigation. The screener decides which of the three routes: health, conduct or performance is the most appropriate.

Health procedures are aimed to rehabilitate the ill doctor whose illness is affecting his or her work. The four stages of the process are initial assessment, medical examination, medical supervision and health committee action. The possible outcomes are suspension, conditional continued registration to practise or a decision that the doctor is fit to practise without conditions. The performance procedures act where there is 'a departure from good professional practice . . . sufficiently serious to call into question a doctor's registration'. Referrals are examined and the doctor is likely to be asked to have a performance assessment. If he or she refuses, the Assessment Referral Committee may order an assessment. The case coordinator uses the outcome of the assessment process to decide that: no further action is required; counselling or training is required; or the case is so serious or the doctor has refused assessment or to agree to retraining such that referral to the Committee on Professional Performance is required. This committee can leave the surgeon's registration intact, impose conditions or suspend or erase. The third channel through the processes of the GMC is the conduct procedures. Here the first relevant filter is the Preliminary Proceedings Committee (PPC). The PPC meets in private and can clear the doctor; refer into the health process; advise or warn the doctor; or refer to the Professional Conduct Committee (PCC). A PCC hearing is, to all intents and purposes, a court of law with a panel, advised by a legal assessor, sitting in judgement. The GMC and the doctor can be represented by barristers if necessary and, unlike the health process, the tone is adversarial. The PCC can postpone a decision and can admonish, suspend or erase the doctor. Sometimes the case is dismissed or the doctor's continued registration is made conditional. Formerly, outcomes of all three processes could be appealed to the judicial committee of the Privy Council but now appeals are heard by the High Court.

Recently, the government has established the Commission for the Regulation of Healthcare Professionals. If it is felt that a decision of the GMC has been too lenient then it is envisaged that the decision can be overturned by this commission in the interests of protecting the public.

There is one more committee of the GMC which is important when the question of a doctor's continuing practice is in doubt. This is the Interim Orders Committee (IOC) to which a doctor may be referred at

the start of any of the three processes. The IOC has powers to impose conditions and to suspend a doctor while the other committees are deliberating. The rationale of the committee is to protect the public from a doubtful doctor while the full process is completed and a fully argued decision of one of the full committees is reached.

All that you have just read about above concerning the GMC is very soon likely to be history. After the Shipman Inquiries a White Paper, *Trust Assurance and Safety – The Regulation of Health Professionals in the 21st Century* was published on February 21, 2007. The Privy Council has extended the term of the 19 elected medical members of the GMC due to stand down on June 30, 2007 until December 31, 2008. This White Paper has several radical proposals which are listed below.

- Doing away with the current standard of proof in fitness to practise cases and replacing it with the civil standard of proof.
- Establishment of an independent body to adjudicate on fitness to practise cases.
- Revalidation will have two parts – relicensing and recertification (which will apply to those on the specialist register and GPs).

The establishment of GMC affiliates to assist employers and the NHS deal with complaints at a local level.

THE HUMAN RIGHTS ACT

Perhaps the two most potentially influential recent statutes affecting surgeons are the Data Protection Act (DPA) (1998) and the Human Rights Act (HRA) (1998). The first of these is discussed under the heading of confidentiality where its effects, although far-reaching, are relatively easy to predict. The effects of the HRA are potentially much more profound but are still being discovered and untangled by current legal cases. In a way this is curious since the HRA formally enshrines in UK legislation, the European Convention on Human Rights.

The European Convention on Human Rights

Many people understand this convention to be a product of the European Community and compliance with it to be a condition of membership. In reality it is a convention to which the UK government signed up in the 1950s. The requirement until the HRA became law was that national legislation should be interpreted in accordance with the convention. The HRA enshrines the rights defined in the convention in UK law, allowing UK citizens to claim in UK courts that their rights have been breached and seek damages or perhaps a stay of criminal proceedings.

A number of rights are described in the HRA and these are divided into qualified and absolute rights. The ones of

most relevance to otolaryngologists are numbers 2, 3, 6 and 8.

Article 2 states the right to life. There are a number of ways in which this is relevant. Perhaps this is another route by which the family of a dead patient may seek redress if there is the suggestion that the death occurred due to corporate or individual error. The verdicts that are open to a coroner are discussed under The criminal law below, but, as described, this important field is changing. The coroner is a public body under the terms of the HRA and so must ensure that verdicts are in line with that act. Will we soon see a verdict of death in contravention of Article 2 of the European Convention on Human Rights returned as a halfway house between death by misadventure and unlawful killing? What would be the consequences for a subsequent negligence claim? If the strong lobby seeking to legalize assisted suicide in certain circumstances is successful, how will this sit with the right to life? It is not clear in the legislation how a patient can personally renounce his or her rights under Article 2.

Article 3 is the right not to be subject to torture or to inhumane or degrading treatment or punishment. This appears to influence the facilities that must be made available by hospitals for the care of patients as well as powerful implications for the whole consent process. Surely it will not be long before a Trust is sued by a patient alleging that the wait on a trolley for 24 hours in casualty constituted inhumane or degrading treatment. There is also a suggestion that the coroner will have to pay regard to Article 3 as well if, in his view, there was inhumane and degrading treatment leading to a death.

There are two other articles with relevance to otolaryngologists: Articles 6 and 8. These two interact with each other when the question of GMC and other legal and paralegal proceedings are considered. Article 6 affirms the right of all citizens to a fair and timely trial. A magistrate in the UK has already stayed a prosecution because he judged that the prosecution had taken an unreasonably long time to bring the case to trial. As the defendant was a doctor and now leaves the criminal court without even having been tried, let alone convicted, it is possible that this judgement will profoundly affect his treatment by the GMC.

Since GMC committees are trials within the meaning of the HRA, they are subject to exactly the same legal liabilities as courts and coroners. It is here that Article 6 may begin to conflict with Article 8, which grants the right to respect for private and family life. Consider the position of a surgeon seeking to refute at the GMC committee on professional performance an allegation that there is a consistent pattern of poor professional competence. In order to defend himself and to liaise with his professional advisers (solicitors and counsel), he would surely need access to the notes of the patients that he cared for and to whom he may have given substandard care. Also, the GMC might wish to call the patients as material witnesses to the substandard care. At present,

there is no obligation on a patient, unwittingly a witness at a GMC committee, to grant consent to release of his or her confidential information to either the doctor or the GMC. The patient has rights under the DPA to know what is being done with his or her data and, except in certain circumstances, to withhold consent for release of that information. The exceptions do not seem to apply to GMC proceedings. Surely a patient who found out that a Trust had divulged notes to a surgeon and his legal advisors or to the GMC, in pursuit of a fair trial, could bring action under both the HRA and the DPA. Perhaps also, a patient or even a doctor other than the one being investigated, obliged by subpoena to attend a GMC hearing as a witness and subsequently hounded by the press, can argue that no respect has been shown to his or her privacy.

The whole question of how the HRA (1998) will affect surgeons is under active consideration at present. The only guarantee in this field is that lawyers will continue to use the act to push the common law in new and unusual directions.

THE CRIMINAL LAW

Otolaryngologists rarely face criminal proceedings in connection with medical practice, but mention should be made concerning two types of criminal offence which may flow from medical treatment.

Involuntary manslaughter

In recent years, an increasing number of doctors have faced the prospect of prosecution following the deaths of their patients, allegedly as the result of medical malpractice. The English law relating to involuntary manslaughter has been in a confused state, and clarification has only very recently been provided by the Court of Appeal. Traditionally, the test for involuntary manslaughter has been one of gross negligence. In the words of the then Lord Chief Justice, Lord Hewart, in the case of *R v. Bateman*,³⁵ in order to establish criminal liability the facts must be such that 'the negligence of the accused went beyond a mere matter of compensation between subjects and showed such a disregard for life and safety of others as to amount to a crime against the state and conduct deserving of punishment'. Adjectives such as 'gross', 'wicked' and 'criminal' were used to describe the degree of negligence required. This is effectively something of a 'gut reaction' test for the jury. In a crime of this nature, it is arguably best left open to the jury to make the determination of criminality.

An attempt was made to further define gross negligence by the House of Lords case of *Andrews v. DPP*.³⁶ In that instance, 'recklessness' was considered to be the adjective which most closely described the concept. In

this way, the House of Lords was endeavouring to ascribe as guilty states of mind the appreciation of risk, coupled with a determination to run it, or the wilful indifference to the question of whether such a risk existed. However, 'mere inadvertence' was not considered to merit criminal responsibility.

The test was thrown into confusion in 1981 as a result of decisions in two cases (*R v. Caldwell* and *R v. Lawrence*)^{37, 38} by the House of Lords which redefined the concept of 'recklessness'. The cases concerned the offences of criminal damage and causing death by reckless driving. It was determined that the defendant would be reckless if his action created an obvious and serious risk (to a victim in the case of manslaughter) and the defendant either appreciated the risk but went on to run it or failed to appreciate the risk. This test has been criticized as being unduly harsh. It allows no realistic explanation of the defendant's state of mind to be put forward. Thus, a doctor under pressure, perhaps through overwork and being asked to perform tasks which he or she should not otherwise have been required to do, would have no opportunity to explain those circumstances as part of defence. The mere fact that an obvious and serious risk had been created to the patient, as a result of which the patient had died, would be sufficient to secure a conviction.

The test was applied in a case of motor manslaughter (*R v. Seymour*)³⁹ by the House of Lords in 1983. Thereafter, however, there was significant confusion as to whether the case should extend to all cases as an involuntary manslaughter. As a result, in some cases involving doctors charged with involuntary manslaughter the traditional test of gross negligence was applied, in others the new harsh formulation for recklessness was considered appropriate. In yet other cases, attempts were made to combine the two tests.

This unsatisfactory situation has been resolved to a degree by the case of *R v. Prentice and Sulliman*.⁴⁰ The case involved two junior doctors, Dr Prentice being a pre-registration House Officer who, as part of the chemotherapy treatment, injected vincristine intrathecally in error. As the Court of Appeal observed, the mitigating circumstances in relation to both doctors were many, but a version of the recklessness test was put to the jury, resulting in their convictions. These were quashed by the Court of Appeal (*R v. Prentice and Sulliman*)⁴¹ on the basis that the test of recklessness was not appropriate for cases of involuntary manslaughter where a breach of duty is concerned, particularly for cases involving doctors, where the court observed: 'Often there is a high degree of danger to the deceased's health, not created by the defendant, and pre-existing risks to the patient's health is what causes the defendant to assume the duty of care with consent. His intervention will often be in situations of emergency.' The traditional test for gross negligence was preferred.

The court set out the matters which need to be established for a prosecution of manslaughter, namely the

existence of a duty of care, the breach of the duty causing death and gross negligence which the jury considers justifies criminal conviction. The Court of Appeal went on to set out various states of mind which it considered could probably lead the jury to making a finding of gross negligence.

- Indifference to an obvious risk of injury to health.
- Actual foresight of a risk coupled with the determination nevertheless to run it.
- An appreciation of the risk, coupled with an intention to avoid it but also coupled with such a high degree of negligence in the attempted avoidance as the jury considers justifies conviction.
- Inattention to or failure to avert a serious risk which goes beyond mere inadvertence in respect of an obvious and important matter which the defendant's duty demanded he should address.

The first three states of mind are not unduly onerous. The fourth, however, may present particular problems to medical practitioners. Medical treatment generally may be considered to amount to an obvious and important matter. Further, many serious risks are inherent in treating patients and, accordingly, medical practitioners remain in danger of falling foul of the criminal law relating to manslaughter. At the conclusion of the judgement of the Court of Appeal in the case of Drs Prentice and Sulliman, the court expressed the view that the Law Commissioners should look at the law in relation to involuntary manslaughter as a matter of urgency, and thus modifications may be made to this area of the law in the near future.

In Canada,⁴² manslaughter may be committed where a doctor causes the death of a patient by, among other things, criminal negligence which may be committed where someone under a duty shows a wanton or reckless disregard for the lives or safety of others. The precise meaning of 'wanton or reckless disregard' is in doubt. In a recent case (*R v. Tutton and Tutton*)⁴³ the Supreme Court of Canada was divided between those who considered that a defendant should have an intention to run a prohibited risk, or a wilful blindness to the risk, and those who considered that a marked and substantial departure from a standard of behaviour expected of a reasonably prudent individual would suffice. This dilemma is similar to that recently addressed by the Court of Appeal in this jurisdiction in the case of Drs Prentice and Sulliman.

In New Zealand (*R v. Yogasakaran*),⁴⁴ the test for manslaughter is that of mere negligence, and a breach of the civil standard of care resulting in the death of a patient is all that is required. Similarly in Greece, the offence under the Greek Criminal Code⁴⁵ is of causing death by negligence, mere civil negligence being sufficient. The charge is often seen as a precursor to civil proceedings, where a victim's family may make complaint to prosecuting authorities, effectively as part of the bargaining process for compensation.

Assault, battery and bodily harm

Charges of assault and battery are considered very infrequently by the prosecuting authorities in this jurisdiction in relation to medical practitioners. Courts are reluctant to consider actions in tort for battery arising out of a failure to obtain consent, let alone criminal charges. Very few doctors will intend to inflict harm on a patient, the overall aim being to provide some form of therapeutic benefit. However, where the clinician performs a procedure which goes substantially beyond that to which the patient has consented and that is known to the clinician, or the clinician is reckless as to whether or not the patient's consent will authorize the procedure actually performed then such an offence may be made out, even if of therapeutic benefit. In circumstances where surgical intervention takes place, an offence of greater seriousness than mere assault may result, for example, assault occasioning grievous bodily harm.

THE FUTURE

It is without doubt that the shift in emphasis is away from the doctor and towards patients' rights. This can clearly be seen in a very recent landmark case (*Chester v. Afshar*)⁴⁶ heard by the House of Lords. Carole Chester agreed to undergo lumbar surgery on the advice of Mr Afshar, a neurosurgeon. She suffered partial paralysis. The judge found that Mr Afshar had not performed the surgery negligently but had failed to warn her of the partial paralysis inherent in the operation. The judge found that she would not have undergone the operation had she been warned but at the time would have sought further advice before deciding on what to do.

'Lord Hope of Craighead said that the claimant could not succeed on conventional causation principles since she did not assert that, if informed, she would never have undergone the surgery and since the defendant's failure neither affected the risk which eventuated nor was the effective cause of her injury. However the causation issue was to be addressed by reference to the scope of the defendant's duty, namely to advise his patient of the disadvantages and dangers of the treatment he proposed; that duty was closely connected with the need for the patient's consent and was central to her right to exercise an informed choice as to whether and, if so, when and from whom to receive the treatment. The function of the law was to enable rights to be vindicated and to provide remedies when duties had been breached. Unless that was done the duty was a hollow one, stripped of practical force and devoid of content. The injury the claimant sustained was within the scope of that duty and might, on policy grounds, be regarded as having been caused, in the legal sense, by the defendant's breach. Accordingly justice

required that the claimant be afforded the remedy she sought.' Lord Steyn and Lord Walker of Gestingthorpe delivered concurring opinions; Lord Bingham and Lord Hoffmann disagreed so the defendant lost his appeal to the House of Lords.

Clearly this has a major impact for no longer does the patient have to state that they would not have had the surgery if they had been aware of all the risks but it is now sufficient for the patient to argue that they would have sought further advice. This has increased pressure on ensuring that specific risks are warned and the warning is recorded. It is now no longer good enough just to record that risks have been explained for a case to be defended where consent is a core issue.

Punitive (exemplary) damages are not normally awarded in jurisdictions of the UK and Australasia but in 2002 the Privy Council heard the case of *A v. Botrill*⁴⁷ from New Zealand. This case involved the wholesale misreading of cervical smears by a private pathologist in Gisborne, New Zealand. Between 1990 and 1994 he examined four smears from Mrs A. After Mrs A had a radical hysterectomy for invasive cancer the smears were reviewed and all four slides had been misread or misreported. Mrs A made a successful claim for accident compensation. Disciplinary proceedings against Dr Botrill found him guilty of conduct unbecoming of a medical practitioner. Mrs A then brought court proceedings claiming exemplary damages. Justice Young dismissed the action applying the principle 'exemplary damages may be awarded, but only if the level of negligence is so high that it amounts to outrageous and flagrant disregard for the plaintiff's safety, meriting condemnation and punishment'.

Two events then occurred: Mrs A found another ten women whose slides had been misread and there was public concern about smear reporting in the Gisborne area. This led to a review of Dr Botrill's slides in Sydney which showed that Dr Botrill's false reporting rate was 50 percent or higher. In the light of the new evidence Mrs A applied for a retrial which was granted. Dr Botrill then appealed this decision and his appeal was successful. Mrs A sought leave to appeal to the Privy Council which was granted. The argument for Mrs A was that cases of reprehensible wrong doing which are totally unacceptable to the community but arise from inadvertent negligence should not be put beyond the reach of exemplary damages. Dr Botrill's argument was that there was no conscious, outrageous and flagrant disregard for the plaintiff's safety. The Privy Council agreed with Mrs A and allowed her appeal on a majority decision.

Although this is a New Zealand case it now brings the possibility of punitive damages for reprehensible wrongdoing even if there was no flagrant disregard of risk. It seems that now inadvertent negligence may lead to exemplary damages in selected cases of the worst kind of professional practice.

KEY POINTS

- Clinical negligence is a matter for civil law.
- Damages awarded are general and special.
- The standard of proof is 'on the balance of probabilities'.
- There are four essential elements of the legal tort of negligence:
 - there must be a duty of care;
 - there must be a breach of that duty;
 - harm must have occurred;
 - the breach must have caused the harm.
- The standard of care is that of the reasonably skilled and experienced doctor.
- 'It will very seldom be right for a judge to reach the conclusion that views genuinely held by a competent medical expert are unreasonable.'
- If the case for each side is evenly balanced then the claimant will fail.
- The court must award a sum of money that will, as nearly as possible, put the injured person in the same position as he would have been had he not been injured.
- The result of the introduction of contingency fees is likely to be that there will be no significant increase in the number of medical negligence actions in the short term.
- Where a proposed treatment involves a substantial risk of grave or adverse consequences such that, notwithstanding any practice to the contrary, a patient's right to decide whether to consent to the treatment was so obvious that no prudent medical man could fail to warn of the risk, then it would be negligent not to warn.
- The parental right to determine whether or not a child under 16 should have medical treatment terminates when the child achieves a significant understanding and intelligence to enable him or her to understand fully what is proposed.
- 'An adult patient who suffers from no mental incapacity has an absolute right to choose whether to consent to medical treatment, to refuse it or to choose one rather than another of the treatments being offered.'
- Any surgeon who keeps any sort of patient identifiable information at his residence and who is not registered with the data commissioner breaches the provisions of the DPA.
- The coroner's remit is to establish the identity of the deceased, the time and place of death and the mode of death.

- Articles 2, 3, 6 and 8 of the HRA are those most relevant to surgeons.
- Modifications to the law on involuntary manslaughter are awaited; currently the traditional description of gross negligence resulting in death usually applies.

INTRODUCTION

This chapter presents epidemiology as a methodological discipline that provides important principles for clinical and health services research. It introduces the 'determinant–occurrence relationship' as a key epidemiological concept. On the basis of this concept, we will demonstrate how epidemiological methods and techniques can be used to address a wide range of questions. This chapter is intended to inform those who want to read the medical literature and evaluate research evidence. In other words, it has been written especially with the needs of the 'consumers' of research in mind.

We will concentrate on the choice of a study design for different types of research questions with the ultimate aim of developing a study that produces results that are relatively precise (free of random error) and accurate (free of systematic error or bias). An additional consideration is that the study needs to be efficient (affordable in terms of time and money). Strengths and weaknesses of study designs will be discussed as much as possible on the basis of examples related to diseases of the ear, nose and throat.

This chapter is not based on a specific literature search strategy. It amalgamates information and points of view as can be found in major textbooks and reviews of epidemiology, methods of health services research and evidence-based clinical practice.

Example: the indication for tonsillectomy

Simple, but well-designed, epidemiological research can be of great importance for clinical practice. A recent

systematic review indicated that the effectiveness of tonsillectomy is uncertain,¹ and in turn, that the indications for tonsillectomy are controversial. Nevertheless, tonsillectomy is one of the commonest surgical procedures carried out in children as well as in adults.

In the 1930s, an estimated 200,000 were performed annually in England and Wales, a huge number compared to an annual number of approximately 40,000 in the year 2000. In the pre-war period, tonsillectomy had become popular to the point of being fashionable, and there was marked variation in its frequency according to geographical location, social class and sex.² It was estimated that at least 85 children lost their lives each year as a direct result of tonsillectomy.

Another study carried out in the 1940s demonstrated that there was great uncertainty about effectiveness and indications,³ as cited in a book by Sackett and coworkers.⁴ Among 389 eleven-year-old schoolchildren with intact tonsils examined by a group of clinicians, tonsillectomy was recommended in 174 (45 percent). A second opinion was requested in the 215 schoolchildren for whom tonsillectomy was not recommended, and tonsillectomy was recommended for 99 (46 percent). The remaining 116 children, in whom on the two previous occasions tonsillectomy was not recommended, were then examined for the third time, and tonsillectomy was recommended in 51 (44 percent) of them. The most remarkable finding is that tonsillectomy was recommended in each of the three cycles for approximately 45 percent of the children.

These historical examples illustrate that uncertainty about diagnostic and management decisions can lead to overtreatment, which may have serious consequences for patients. Given the fact that there is still no high-quality

evidence on the effectiveness of tonsillectomy more than 50 years later, the same problem may still exist, albeit to a lesser extent. The only published study on the effectiveness of tonsillectomy that could be included in one systematic review studied 91 children and was affected by important baseline differences in the characteristics of the surgical and the control group.¹ It is obvious that this kind of clinical uncertainty can only be solved by epidemiological evidence of high quality.

WHAT IS EPIDEMIOLOGY?

Epidemiology is a relative young discipline, but during its short life many definitions of epidemiology have emerged.⁵ Many of these describe epidemiology in terms of its subject matter. The perhaps most frequently cited definition in this context states that **epidemiology is the study of the distribution and determinants of disease frequency in human populations.**⁶ These three closely related components – **distribution, determinants and frequency** – encompass many epidemiological principles and methods.⁷ For example, an epidemiological study that would fit perfectly within this definition is that of the frequency of head and neck cancer in a certain geographical area. This study could also consider the distribution of the disease among different subgroups. The determinants of disease occurrence would then derive from these two.

Although this definition has its merits in that it covers many epidemiological studies, some of which attracted large media attention (for example, smoking and lung cancer, cholesterol and heart disease, effect of di-ethylstilbestrol on offspring, unprotected sex and the acquired immune deficiency syndrome), a growing number of epidemiologists feel that the above-cited definition does not cover their work. The reason is that the subject matter of what can be considered epidemiological studies has become rather heterogeneous. Attempts to produce a definition of epidemiology based upon its subject matter therefore produce confusion rather than clarity.

The concept of the determinant–occurrence relationship

In the last two decades, **an alternative definition** has arisen that defines **epidemiology as a discipline that studies the functional relationship between the occurrence of disease (or related health outcomes) and its determinants.**⁸ This may seem a trivial step, but this focus on the concept of the ‘determinant–occurrence relationship’ rather than the subject matter has considerably broadened the scope of epidemiology in medicine.

One of the major reasons why epidemiology has gained such far-reaching importance lies in the nature of medical knowledge. Medical knowledge is, to a large extent,

derived from the experience obtained in groups of similar patients. Medicine is therefore an empirical science, and many of the empirical relationships in medicine can be considered as determinant–occurrence relationships. It is especially this realization on the basis of which epidemiology has become a basic science in medicine.

Epidemiology as a methodological discipline

An alternative approach to clarify the definition of epidemiology is to consider it as a methodological discipline. From this perspective, the subject of epidemiological inquiry is not so much the determinants of the occurrence of disease and other health outcomes, but the principles and methods for the study of determinant–occurrence relationships.

As a methodological discipline, epidemiology allows a large number of different questions to be answered. As explained earlier, it may play a role in describing the distribution of health and disease in a population. Who is affected? Where and when does this health problem occur? Why does it occur in a particular population?

However, other questions can be considered as well. Once a health problem occurs, epidemiology also provides methods for monitoring the course and outcome of a health problem. What is the outcome of the health problem? It may answer questions regarding the outcomes of interventions. Is intervention A more effective than intervention B? How well does a diagnostic test distinguish between people with and without the target disorder?

Epidemiological research is also essential for the assessment of the burden of disease and the need for health services and evaluation of the access to services. How much suffering does this health problem cause in a population? How many people need a certain intervention? Who uses the intervention? What factors explain differences in health care use?

‘STREAMS’ OF EPIDEMIOLOGY

Given the extension of the boundaries of epidemiology – based on the introduction of the determinant–occurrence relationship as the key epidemiological concept and the realization that epidemiological principles provide the methodological underpinning for the study of a wide range of questions – one can recognize several ‘streams’ of epidemiological research. These streams differ largely according to the types of questions they address, but they share most of the methodological concepts and principles.

Classical epidemiology

The first stream of research is ‘classical epidemiology’, sometimes referred to as ‘aetiological epidemiology’ or

'risk factor epidemiology', of which the ultimate goal is 'the elaboration of causes that can explain patterns of disease occurrence'.⁵ The geographical distribution of a disease, the variations in its frequency over time, and the special characteristics of people affected by it, are typical objects of study.

There is often a natural progression in this type of epidemiological research.⁷ First, there is a concern about the possible influence of a particular factor on the occurrence of disease. This suspicion can have many origins – clinical practice, laboratory research, theoretical speculation – but it often arises from examination of disease distributions, and leads to the formulation of a specific hypothesis about its causes. It can then be further explored in studies of individuals that include an appropriate comparison group. A systematic collection and analysis of data may reveal that a statistical association exists. It is then essential to assess whether random errors or systematic errors might be responsible for the findings. Finally, a judgement needs to be made about whether an observed association represents a cause–effect relationship.

An otolaryngological example of this type of epidemiological research is the study of the distribution of head and neck cancers and the association of the occurrence of this disease with traditional risk factors such as diet, smoking and drinking habits or socioeconomic status. Another more specific example is the testing of the hypothesis that there is a link between human papillomavirus and the occurrence of a subset of these cancers. The result of aetiological research may guide the first steps towards the development of primary prevention that keeps disease from occurring at all.

However, the reductionist nature of classical epidemiology has been criticized. It has been argued that epidemiological studies often ignore 'the interdependence of multiple agents and how human populations become exposed and susceptible to them'.⁹ Epidemiological research that focuses on the effect of risk factors measurable at the level of the individual neglects the population context and the social and cultural determinants that act at population level.

Clinical epidemiology

The second stream of research is 'clinical epidemiology'. The adjective 'clinical' is added because clinical epidemiology 'seeks to answer clinical questions and to guide clinical decision making with the best available evidence'.¹⁰ Clinicians are mainly concerned with problems of individual patients. It may seem paradoxical that results of epidemiological studies that are derived from groups of patients should be applicable to the problems of individual patients. It is obvious, however, that this is because the best evidence to solve a clinical problem is derived from the experience of a large number of similar patients.

Advocates of evidence-based medicine have addressed this paradox directly. They state that clinicians need to carry out 'the particularization, to the individual patient, of our prior experiences (both as individual clinicians and collectively) with groups of similar patients'.⁴ A good clinician should therefore use the best available external evidence together with his own unsystematic clinical experience and intuition – based on a blend of knowledge derived from anatomy, physiology and other basic sciences.¹¹ Evidence alone is never sufficient to make a clinical decision. Decision-makers always trade the benefits and risks, inconvenience and costs associated with alternative management strategies, and in doing so should especially consider the patients' values and preferences.

The significance of the definition of epidemiology as a methodological discipline that addresses determinant–occurrence relationships is based on the reach of the concept of determinant–occurrence relationships in itself. If one considers the presence of disease as the outcome and the diagnostic information as the determinant, then this represents a diagnostic problem. The object of study is, in this case, the functional relationship between diagnostic information and the presence of disease. If one considers the occurrence of a disease or a health-related event in the future as the outcome and the presence of certain patient characteristics as the determinants, then this represents a prognostic problem. One of these patient characteristics can be the use of a specific therapy, and in that case, this represents a therapeutic problem. In the latter case however, to achieve accurate results the '*ceteris paribus* principle' – the condition that all other determinants are equal – is a fundamental notion that we will explicitly address under Randomized controlled trials.

A study of the diagnostic accuracy of fine-needle aspiration as a test for malignant disease in patients with nodular thyroid disease is an otolaryngological example of diagnostic research. The influence of the age of patients with an oropharyngeal carcinoma on long-term survival constitutes a prognostic research question. The effect that early surgery compared with watchful waiting for glue-ear has on language development in preschool children represents a therapeutic research question.

Epidemiology and health services and public health research

Epidemiology is also one of the core disciplines of health services research and public health. Whereas classical epidemiology and clinical epidemiology focus largely on determinants of health and disease and related conditions in individuals, health services research is more directed towards questions addressing the quality and organization of health care systems and public health research towards the health and health care problems in communities. One

could consider this as a third stream of epidemiological research.

Important questions for health services research are those that address the variations in processes and outcomes of health care services, as well as the determinants of these variations. Research in public health may be concerned with the influence of environmental factors, socioeconomic conditions and health services on health in the community. It will be clear by now that many of these questions take the form of determinant–occurrence relationships, which again confirms the crucial role of an epidemiological approach.

A study comparing the outcome of thyroid surgery performed by experienced surgeons and surgeons in training is an example of an epidemiological study directly addressing a determinant of the quality of otolaryngological care.¹² Another example is a study of the impact that the publication of a guideline on the treatment of persistent glue-ear in children had on the rate of surgery.¹³ A systematic review of studies addressing the effectiveness of screening young children to undergo early treatment for glue-ear is a third example of public health research.¹⁴

THE 'ANATOMY' AND 'PHYSIOLOGY' OF EPIDEMIOLOGICAL RESEARCH

We cannot discuss the different study designs before we have examined what epidemiological research is made up of and how it works. The easiest way to do this is to describe the components of a study protocol and the way results are used to draw inferences from the study results about the truth in the universe. The following sections are based largely on the introductory chapters of a recent book by Hulley and colleagues about designing clinical research.¹⁵

Essential components of a protocol for an epidemiological study

A research protocol is a document that provides all essential details of a study. A protocol is necessary for guiding all the decisions that need to be made in the course of the study. The process of writing a protocol itself helps the investigator to enhance the scientific rigour and efficiency of the project. Most research involves teamwork and a written document ensures that all members know how the study should be implemented and what they are expected to contribute. A good protocol provides answers to a number of essential questions.

WHAT QUESTION WILL THE STUDY ADDRESS?

The research question defines what you want to achieve. Many experienced researchers will agree that formulating

a question that can be translated into a feasible and valid study can be surprisingly hard. What often happens is that instead of a 'research question', a 'topic' is formulated. 'Framing' the research question is the first step for every new project, of which the importance cannot be overestimated. Conversely, many studies fail not so much because the study design is flawed or the execution of study is poor, but because the question was not formulated adequately in the first place.

An otolaryngological example of such a 'topic' that needs further research is the concern about the rising complication rate after tonsillectomy in the UK. It is clear that we need to provide more detail and structure before we are able to formulate a relevant and answerable 'research question'. The concept of the determinant–occurrence relationship may provide some guidance in this context. In other words, we need to be specific about what outcomes we want to study as well as what determinants we want to consider. Finally, we need to specify the target population, the kind of people for whom the study should provide answers.

In epidemiological research, a good research question therefore has three components. It should define:

1. the target population;
2. the comparison or control group, at least if there is any;
3. the outcome(s) of interest.

An example of a 'good' research question for a study addressing the complication rates after tonsillectomy could be: 'In patients undergoing tonsillectomy because of recurrent tonsillitis, does the use of the bipolar diathermy forceps increase the occurrence of tonsil bleeds severe enough to require return to theatre in the first 28 days after surgery, compared to other tonsillectomy dissection types?' Admittedly, this is a rather convoluted sentence, and is only given here to illustrate how the three components of a research question can be covered in one question. In practice, the question will be shortened to 'Does bipolar diathermy increase the haemorrhage rate after tonsillectomy', but in that case the details that define the target population, the comparison and the outcome of interest need to be provided separately.

WHY IS THE STUDY QUESTION IMPORTANT?

Good epidemiological research should also pass the 'so what' test. In the Introduction or Background section of a protocol, it should be argued that answering the research question will provide a significant contribution to our state of knowledge or, in other words, add to what is already known about the problem. It is therefore important to be on top of the published literature before developing a study. It should also be clear that the results of the proposed study will help to resolve current uncertainties, which may lead to new scientific understanding and influence clinical and public health policies.

It is often 'scholarship' that will identify the gaps in the current knowledge and how these can be addressed in an optimal way by learning from the work of others. For example, a recent systematic review of the literature on the effect of tonsillectomy in patients with chronic or recurrent tonsillitis concluded a lack of evidence to guide decision making for this surgical intervention in adults or children.¹ More importantly in this context, the authors of the systematic review also concluded on the basis of the results of their review that future trials should address the effectiveness of tonsillectomy in subgroups according to age, severity and disease frequency, and that patients should be followed up for at least one year to assess outcomes such as general well-being, behaviour, growth, sleep and eating patterns in addition to severity and frequency of infections. These conclusions based upon a systematic review provide powerful arguments for the direction of future research.

HOW IS THE STUDY STRUCTURED?

Choosing the study design is a complex issue. The actual choice depends strongly on the research question. The study should be designed in such a way that it produces results that are relatively precise (free of random error) and accurate (free of systematic error or bias). An additional consideration is that the study needs to be efficient (affordable in terms of time and money).

A simplistic 'taxonomy' of study designs, presented in **Figure 49.1**, shows that two fundamental decisions have to be made. First, the investigators have to decide whether they want to assign the determinants themselves in an 'experimental study', or whether they want to examine events as nature takes its course in an 'observational study'. Second, if an observational study design is chosen,

the next step is to decide whether the study needs a comparison or control group. If so, the study is often called 'analytical'. If not, it is a 'descriptive' study. Descriptive studies are often used as a first step into a new area of study – the scientific 'toe in the water',¹⁵ and followed by analytical studies to answer questions that can address determinant–occurrence relationships.

A more detailed presentation of study designs follows under Choosing the study design.

WHO ARE THE STUDY SUBJECTS AND HOW WILL THEY BE SELECTED AND RECRUITED?

A good choice of the study subjects ensures that the results of the study will accurately represent what is going on in the population of interest, the target population, the set of people best suited to the research question (for example, patients with early laryngeal squamous cell carcinoma for a study comparing radiotherapy and surgery for laryngeal cancer). The protocol must also specify the study sample, which is the subset of the target population available for study (for example, all consecutive patients with this disease condition referred to a regional head and neck cancer centre in a defined period of time). The study sample should be a subset of the target population that can be studied at an acceptable cost and is large enough to control random error and representative enough to control systematic error.

In many cases, controlling both random error and systematic error sets conflicting demands, which is sometimes referred to as the 'precision–bias' dilemma. For example, a study that aims to evaluate the usefulness of the endoscope compared to the headlamp for sinonasal surgery should carefully consider which patients to include. It is highly likely that the results of the study

Very Important:-

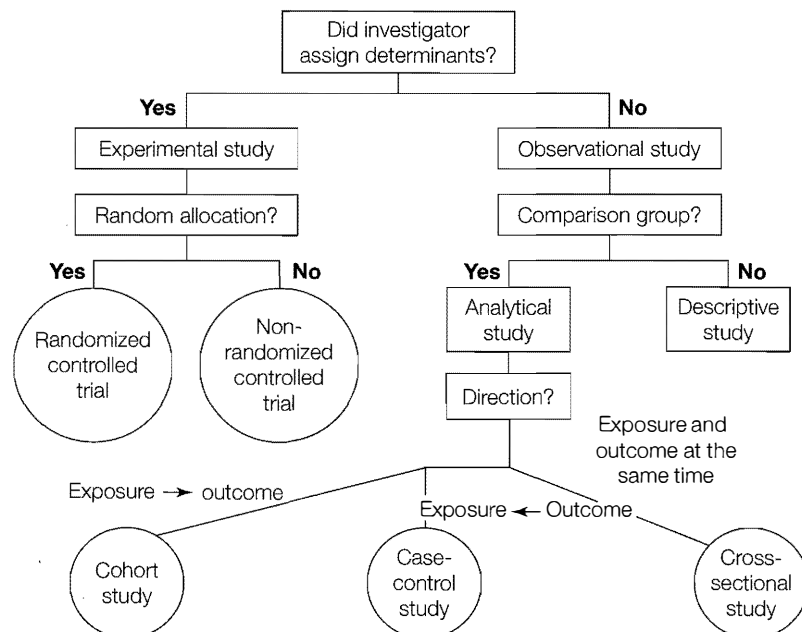

Figure 49.1 Algorithm for classification of types of clinical research. Reproduced from Ref. 16, with permission from Elsevier.

will differ according to the extent of the surgery. The comparison might be most relevant for patients who undergo surgery for procedures around the middle meatus and the anterior ethmoid. Including patients who undergo only simple polypectomy, who comprise approximately 50 percent of the total number of patients who undergo a form of sinonasal surgery, may seem an attractive option because it will double the size of the study. However, including these patients will diminish the extent to which the study sample represents the population for which the research question is of interest.

In an ideal world without practical and financial limitations, we would study the entire target population. Often, if not always, the target population is too large and the study will be carried out in a sample. Earlier, we gave as an example the study comparing radiotherapy and surgery for early laryngeal carcinoma that was carried out in consecutive patients visiting a regional centre in a defined period of time. This type of sampling, including patients that are easily accessible to the investigator, is called 'convenience sampling'. It is very frequently used in clinical research. It has obvious advantages in terms of costs and logistics, but its drawback is that it might not sufficiently represent the target population. Consecutive sampling, including without interruption all accessible people, is especially useful in this context given that it reduces the possibility that selection either by the investigators or self-selection by the subjects influences the results. Probability sampling is the gold standard for ensuring that the study sample is representative of the target population, except for the effect of chance variation. There are several probability-sampling methods. With simple random sampling, every individual in a population has the same chance of being included. However, in some cases, a form of stratified sampling (random sampling with a known sample size within subgroups) is desirable. For a study of patient satisfaction of patients visiting an otolaryngology outpatient clinic, for example, the investigators may wish to divide patients in 'strata' according to their diagnosis or the procedure that was being carried out, and then sample specified numbers from each stratum.

The choices made about the selection of the study subjects (the intended sample) are important as they have an impact on the extent to which the study findings can be generalized. The sampling procedures can affect the generalizability of the results in a number of ways. First, the actual sample might be different from the intended sample. For example, people who were eligible for the study might have refused, and people who participated might be different (more or less healthy, dependent on the study context) from those who did not. Second, the study sample should be sufficiently similar to the target population. For example, the 'spectrum' of disease in patients with laryngeal squamous cell cancer might differ from one centre to the next, and in turn the effects of radiotherapy and cancer might differ as well. Third, the

investigator must form an opinion about whether the results can be generalized to people outside the target population. In terms of our example, do radiotherapy and surgery have similar effects in other countries, in patients with more advanced disease, or in patients who are on average older or younger? This will always be a subjective judgement that depends on findings in other studies, more general scientific knowledge, and what is sometimes called 'a feeling for the organism'. It is not a yes-or-no decision, and may trigger debate among experts. This debate may be informed by the study itself if the study population is diverse enough to explore the constancy of effects in different subgroups within the study.

WHAT MEASUREMENTS WILL BE MADE?

The quality of a study depends on how well the variables measured in the study represent the phenomena of interest. Another concern is how the variables of interest can be measured as precisely (free of random error) and accurately (free of systematic error) as possible without making the study unreasonably expensive.

It is important to have some understanding about the types of variables that are encountered in epidemiological research, and how they can be measured. Any variable can be considered to be of one of two basic types: continuous variables and categorical variables. This distinction determines the way in which these variables should be measured as well as analysed. As a general rule, with categorical variables, the analysis will involve a description or comparison of the proportion of subjects falling into the various categories. With continuous variables, the descriptions or comparisons are most often presented in terms of average values or medians if the sample is small and the average value is considered to be inappropriate to describe the 'midpoint' of the variable's distribution.

Theoretically, continuous variables can take all possible values on a continuum along a specific range. Many clinical parameters are continuous. Variables, such as blood pressure, body weight, body temperature, are not restricted to particular values and are only limited by the accuracy and precision of the measuring procedures. The units in which a continuous variable is expressed specify a uniform difference along the entire length of the scale. A difference in blood pressure of 10 mmHg has the same interpretation irrespective of whether it occurs at the lower or the upper end of the blood pressure scale.

Discrete variables can only take certain numerical values – in most cases only integers (whole numbers). If discrete variables have a considerable number of possible values, they can often be treated as if they were continuous. Examples of these 'quasi-continuous' variables are counts (such as the number of cigarettes smoked, number of episodes of acute tonsillitis in last year, or number of days spent in hospital) or scores on 'clinimetric scales' (such as the 20-item Sino-Nasal Outcome Test) that measures symptom severity of sinonasal conditions on a scale with

discrete values ranging from 0 (no symptoms) to 100 (very severe symptoms)¹⁷ or the Epworth Sleepiness Scales, used in patients with obstructive sleep apnoea, that can take discrete values from 0 (no daytime sleepiness) to 24 (very severe daytime sleepiness).¹⁸ Strictly speaking, considering scores on a clinimetric scale as continuous is somewhat problematic, as the interpretation of a difference of one unit may vary along the length of the scale. For example, does an increase from five to ten on the Epworth Sleepiness Score correspond to an increase from 15 to 20?

Phenomena that cannot be measured quantitatively can often be measured by classifying them into categories, and then counting the number of subjects that fall within the defined categories. In its simplest form, there are only two categories (such as man/woman, or dead/alive), and these variables are called dichotomous or binary variables. When there are more than two possible categories, the variables are termed poly- or multichotomous variables. Polychotomous variables can be further classified into those that are ordered, called ordinal variables, and those that are not, called nominal variables. Socioeconomic status, ASA grades describing fitness to undergo surgery,¹⁹ and degree of pain are examples of the former, and race, marital status, and blood type are examples of the latter.

As a general rule, continuous variables are more 'informative' than categorical variables. It is therefore advisable to use continuous variables as much as possible. For example, 'body temperature' as a continuous variable should be preferred to a categorical variable dividing patients into those with a temperature below and above a certain threshold.

Good measurements are precise and accurate. There are largely three sources of random and systematic error: (1) variability due to the observer; (2) variability due to the subject; and (3) variability due to the instrument used.

A number of strategies can be followed to increase simultaneously both precision and accuracy of the measurements. First, the measurement procedures should be standardized and clearly described in the study protocol. Second, those who are involved in taking the measurements should be trained and their performance monitored in the course of the study. Third, the measurements should be carefully chosen in terms of what is known about their performance. Fourth, calibration procedures should be carried out against a 'gold standard'. This is especially essential for mechanical devices such as weighing scales, thermometers and blood pressure measuring devices. Furthermore, a simple and rather effective approach to increase measurement precision is to repeat the measurements and to use the mean of two or more observations. The latter approach is commonly used in studies measuring blood pressure. An important approach to reduce systematic error is blinding, which conceals information about determinants, or in some cases outcomes, to the observers and/or

subjects. This reduces the possibility that the observers or the study subjects distort the overall accuracy of the measurements, consciously or unconsciously. Blinding, however, does not ensure overall accuracy of the measurements, but it may eliminate 'differential bias' that affects one study group more than another. Blinding is especially relevant for measurements that incorporate some subjective judgement. For example, a study comparing early surgery with watchful waiting for glue-ear in pre-school children used a tester of language development who was unaware of what treatment the children had received.²⁰

HOW WILL THE RESULTS BE ANALYSED?

The main statistical methods that are going to be used to analyse the results should be defined in the study protocol. Choosing the statistical methods after the results have become available will increase the likelihood of finding associations between determinants and outcome on the basis of chance alone.

An important element of the analysis plan is the description of how the outcome variable is going to be analysed. For example, a trial on early surgery for glue-ear that measured language development with the Reynell development language scales (a test of expressive language and verbal comprehension abilities in children aged six months to six years) could analyse the Reynell data as a continuous variable.²⁰ Conversely, it could define groups with normal language development and with delayed language development by dichotomizing the Reynell data, and use this categorical variable as the main outcome measure.

If a categorical variable is used as the outcome measure, the 'denominator problem' should be considered. **Figure 49.2** summarizes the questions that have to be answered in this respect. The first question asks whether the numerator is going to be included in the denominator. If the answer is yes, the next question is whether time is included in the denominator or not.

Let us first consider the case when the numerator is included in the denominator, but time is not. A first example of this would be a measure of the occurrence of sensorineural hearing loss in neonates. One could simply report the proportion of neonates with hearing loss: the numerator would be the number of neonates with hearing loss and the denominator would be the total number of neonates included in the study. This proportion is often referred to as prevalence. A second example would be a measure of the occurrence of head and neck cancer in people, initially free of the disease, who developed the disease within a specified time period. The numerator would be the number of subjects who developed the disease during follow up and the denominator would be the total number of subjects at the beginning of the study. This proportion is often referred to as cumulative incidence. Suppose that 1000 smokers are followed up

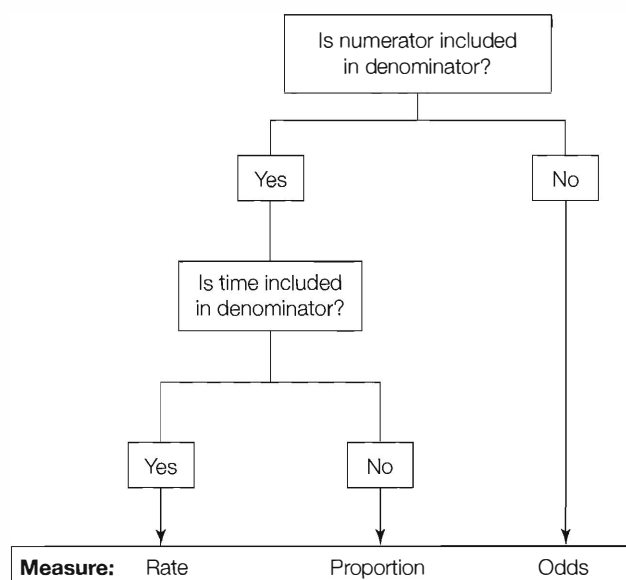

Figure 49.2 Algorithm for distinguishing rates, proportions and odds. Adapted from Ref. 16, with permission from Elsevier.

during five years and that 15 develop head and neck cancer, the cumulative incidence would be 1.5 percent.

The calculation of a proportion as an estimate of disease occurrence, as described above, assumes that the entire study sample has been followed up for the specified time period. This is often not the case. Some subjects might enter the study later, and others might be lost to follow up. An alternative way of measuring outcomes that takes these varying follow-up time periods into account is to include time in the denominator. The numerator would be exactly the same as for proportions, but the sum of the time that each individual was followed up and at risk of becoming a case would be used as the denominator. In this case, an incidence rate (also called incidence density, force of morbidity/mortality, hazard) could be calculated that is equal to the number of people who develop cancer divided by the total person-time at risk during follow up. For example, on the basis of the previous example of the occurrence of head and neck cancer in smokers, one could have expressed the incidence rate of cancer as approximately three cases per 1000 people per year (or 15 divided by approximately 5×1000 years of person-time at risk). Because the incidence is very low, a simple relationship holds: cumulative incidence \approx incidence \times average follow-up time.

Many epidemiological studies report, in some form or other, outcomes expressed as 'odds'. It is important to distinguish odds from probability. A probability can be estimated as the proportion of people in whom a particular characteristic, such as the presence of disease, is present. The larger the group of people under study, the better the observed proportion of people with the disease reflects the 'true' probability. Odds, on the other hand, represents the ratio of two complementary probabilities.

Table 49.1 'Outcome odds ratios' and 'determinant odds ratios' – fictitious example of complication rates after tonsillectomy.

Dissection instruments used	Postoperative complication			
	Yes	No	Total	
Bipolar diathermy	36 <i>a</i>	264 <i>b</i>	300	<i>a</i> + <i>b</i>
Other	24 <i>c</i>	676 <i>d</i>	700	<i>c</i> + <i>d</i>
Total	60 <i>a</i> + <i>c</i>	940 <i>b</i> + <i>d</i>	1000	

For example, if the probability of disease is 0.20, then the odds are $0.20\% / 0.80 = 1:4 = 0.25$. Another way of calculating the odds is by dividing the number of subjects with the characteristic by the number without it. In other words, the numerator is not included in the denominator (see **Figure 49.2**).

Most frequently, it is not the odds itself that is reported in epidemiological studies, but the odds ratio – the ratio of odds in different groups. This can be the 'outcome odds ratio', or the ratio of the odds of the outcome of interest in the group with the determinant to the odds of the outcome in the group without the determinant. Conversely, this can also be the 'determinant odds ratio', or the odds of the determinant in the group with the outcome compared to the odds of the determinant in the group without the outcome of interest. One reason why epidemiologists find odds ratios so attractive is that 'outcome odds ratios' are equivalent to 'determinant odds ratios', which is a fact used in the analysis of case-control studies (see Case-control studies). For example, **Table 49.1** presents fictitious findings of a study on risk factors for postoperative complications after tonsillectomy. The outcome odds ratio is the same as the determinant odds ratio, which can be easily understood as both odds ratios simplify to the 'cross product' of the cell frequencies of a 2×2 table. The 'outcome odds ratio' can be calculated as

$$\frac{\frac{a}{a+b} / \frac{b}{a+b}}{\frac{c}{c+d} / \frac{d}{c+d}} = \frac{a/b}{c/d} = \frac{a \times d}{b \times c} = \frac{36 \times 676}{24 \times 264} = 3.8.$$

Similarly, the 'determinant odds ratio' can be calculated as

$$\frac{\frac{a}{a+c} / \frac{c}{a+c}}{\frac{b}{b+d} / \frac{d}{b+d}} = \frac{a/c}{b/d} = \frac{a \times d}{b \times c} = 3.8.$$

When a dichotomous outcome variable is used (for example, alive/dead, or disease present/absent) 'risk differences' and 'risk ratios' are commonly used as 'measures of effect'.¹⁰ The 'risk' in this circumstance can represent 'prevalence', 'cumulative incidence', 'incidence' or even 'odds', as described above. One might ask, 'What is the additional risk of head and neck cancer in people who smoke, over and above that in people who do not?' The answer to this question is obviously a risk difference. In a previous fictitious example, we supposed that we

followed up 1000 smokers for a period of five years and that we found that 15 of them developed head and neck cancer. The cumulative incidence of cancer in this group is therefore 1.5 percent. We can also suppose that we did the same in 1000 nonsmokers and that we found cancer in seven of them. The cumulative incidence in nonsmokers is 0.7 percent. The risk difference attributable to smoking is therefore 0.8 percent ($= 1.5 - 0.7$ percent). On the other hand, one might ask, 'How many times are smokers more likely to get head and neck cancer compared to nonsmokers?' Following our example, we could calculate the risk ratio as 2.1 ($= 1.5$ percent / 0.7 percent). In other words, smokers are approximately twice as likely to develop head and neck cancer over a five-year period as nonsmokers. This risk ratio does not tell us anything about the magnitude of the risk difference. Even for large risk ratios, the risk difference might be quite small if the outcome is uncommon. As a rule of thumb, risk differences are more meaningful as a measure of effect in clinical situations, because it represents the actual additional probability in those exposed. On the other hand, relative risks are more meaningful as effect measures of a causal relationship in aetiological studies.

HOW LARGE IS THE STUDY GOING TO BE?

A major problem of many studies is that the study size is too small. Small studies lead to imprecise results. Small studies often increase, rather than reduce, the scientific and clinical uncertainty in a specific area. Although one might argue that small studies have a value of their own because they might be included in a systematic review and meta-analysis, which would mimic the results of a larger study, it should be the goal of every study to include a number of subjects that would in itself produce 'meaningful' results. A considerably less frequent problem is that of a study that is larger than necessary to be meaningful. Larger studies are more difficult to carry out and may be more costly than necessary. The most important issue in this context is of course to determine what can be considered meaningful.

How can the appropriate size of a study be determined? This question is most commonly answered on the basis of a statistical 'sample size calculation'. Although the answer of a sample size calculation is exact (for example, the number of subjects to be included in a study), in many cases it depends on a number of rather subjective choices. The way that the sample size of study is to be calculated depends on whether it is an analytical study (study with a comparison or control group) or a descriptive study.

For analytical studies, a research hypothesis should be formulated that further refines the study question. This hypothesis sets out the basis for statistical significance testing. Because this hypothesis guides the statistical analysis, it should be simple (addressing one determinant

or comparison and the occurrence of one outcome) and specific (defining unambiguously the target population, the control and comparison group, and the outcome of interest). For the purpose of statistical significance testing, this hypothesis should be given in the form of a 'null hypothesis' that states that there is no association between the determinant and the outcome. A statistical test helps to estimate the probability that an association observed in a study is due to chance (the ' p -value'). The 'alternative hypothesis' states that there is such an association. Sometimes, a distinction is made between one-sided and two-sided hypotheses. Two-sided hypotheses state only that an association exists between determinant and outcome, whereas one-side hypotheses specify the direction of the association. For example, the null-hypothesis of a study comparing early surgery with watchful waiting for glue-ear in pre-school children could be that there is no difference in the language development in the two treatment groups. The one-sided null hypothesis would state that language development with early surgery is poorer than with watchful waiting. One-sided p -values are appropriate in selected circumstances, when only one direction of the association is important. One-sided p -values may seem attractive as, generally speaking, with a one-sided significance test the p -value would be half the size of that with a two-sided test, but, on the other hand, if the results of the study would suggest that the language development is indeed poorer with surgery, then this would produce a large p -value as it is likely to observe a result like that given that the null-hypothesis (language development with surgery is poorer) is true. For this reason, it is convention to use two-sided hypotheses when planning the size of a study as well as two-sided p -values when analysing the results, unless there are well-argued reasons for the contrary.

When developing a study protocol for an analytical study, the investigator does not know the size of the effect that the determinant of interest has on the outcome, as one of the objectives of the study is to estimate it. For example, the investigators of the study of the effect that early surgery has on language development in children with glue-ear had to decide the smallest effect of surgery that in their view would be of clinical importance. This quantity is often called effect size or target difference. Determining this effect size is the most arbitrary step in a sample size calculation. The smaller the effect size, the larger the study needs to be, other things being equal. Previous studies could help to make a guess about what can be expected, but they do not provide any guidance about what is an important difference and what is not.

Before a sample size can be calculated, two further arbitrary choices need to be made. First, the 'alpha level' or 'significance level' has to be chosen that defines the cut-off point for the p -value – conventionally 0.05 – to classify a result either as 'significant' (if p -value \leq cut-off), in which case the null hypothesis is rejected, or as 'not significant' (if p -value $>$ cut-off), in which case the null

hypothesis is not rejected. Second, the ‘power’ of the significance test has to be chosen – commonly used values are 0.80 or 0.90 – that defines the probability to obtain a significant result if we assume that the defined effect size or target difference would be the ‘true effect’ or ‘true difference’.

Finally, and only if a continuous outcome variable is going to be analysed, a measure of the variability (spread) of that outcome – standard deviation or variance – is needed. The greater the variability in the outcome variable among the subjects, the more difficult it will be to demonstrate a difference between two groups, and the larger the study needs to be.

The required sample size can be obtained on the basis of the above-described ingredients either by using the formulae presented in statistical textbooks, from published tables or by using commonly available statistical software packages. The ingredients and the formulae for study size are purely technical. They do not take into account the value of the information obtained in the study. The most important decision is to determine the ‘right balance’ between the value of greater precision in study results against the greater costs. Essentially, this decision boils down to a cost–benefit analysis in which the benefits are more difficult to quantify than the costs.

For descriptive studies, concepts such as null hypothesis, effect size, alpha level and power do not apply. Instead, descriptive statistics, such as means and proportions, are presented. The sample size of descriptive studies depends on how precise the investigator wants these descriptive statistics to be. Confidence intervals, such as 95 or 99 percent confidence intervals, are commonly used to represent the precision of the estimates. For example, a study of the five-year survival after surgical treatment in 228 patients with hypopharynx carcinoma found that the survival was 27.2 percent with a 95 percent confidence interval ranging from 21.5 to 33.5 percent.²¹ This interval indicates that we can be 95 percent confident (which can be considered more or less the same as saying that there is 95 percent chance) that the ‘true’ five-year survival probability lies within this interval. When estimating the sample size for descriptive studies, the investigator specifies the desired width of the confidence interval, and the sample size derives from that and can be read from tables or obtained from statistical software packages. This approach can be followed for any type of descriptive variable for which confidence intervals can be calculated.

CHOOSING THE STUDY DESIGN

The taxonomy of study designs presented in **Figure 49.1** provides a simple decision aid for choosing the most appropriate design. A number of questions have to be answered with the ultimate goal being to create an affordable study that provides results that are relatively

precise (free of random error) and accurate (free of systematic error or bias). A first distinction that has to be made is that between studies in which the investigator actively assigns the determinants (experimental studies) or those in which this is not the case (observational studies). A second distinction that has to be made is that between observational studies that do or do not have a comparison or control group. If so, the study is called analytical, if not, descriptive.

The following sections are largely based on a series of short essays on clinical research published in the *Lancet*,¹⁶ and chapters of recent books about designing clinical research by Hulley and colleagues¹² and clinical epidemiology.¹⁰ We start this section by describing observational studies and will end with the description of experimental studies (randomized controlled trials).

Minimizing bias and confounding

We have indicated earlier that the precision of study results depends mainly on two factors: the size of the study design and the methods used to obtain the measurements. Furthermore, a study should be designed in such a way that it avoids systematic error or bias. A great number of different types of bias have been documented but it is not a major simplification to consider all these types of biases in three categories: selection bias, information bias and confounding.

To examine whether selection bias would introduce systematic error in the study results, two questions need to be answered: ‘Do the sample of study subjects sufficiently represent the population of interest?’ and ‘Are the groups that are going to be compared similar in all important respects apart from the determinant(s) of interest?’ The first question is especially relevant when designing a randomized controlled trial, because trials usually enrol patients who tend to be different (often healthier) from the target population and the results tend to overestimate the effects compared to what they would be in routine practice. This contributes to the differences between the efficacy of a therapy observed in the highly controlled circumstances in selected clinical settings and the effectiveness of a treatment in actual practice. The second question refers directly to the comparability of the groups. In other words, do the groups differ importantly aside from the comparison that is being studied?

Information bias results from incorrect information about the determinant or the outcome or both. The important question that has to be answered is: ‘Has information been gathered in the same way?’ In cohort studies (see Cohort studies), information about the outcome should be obtained in the same way for those with and without the determinants under consideration. Also, those who collect the information about the outcome should be unaware of (‘blind to’) the determinant status of the subjects as much as possible. In

case-control studies (see below), information about the determinant status should be collected in the same way for cases and controls.

Confounding occurs when two determinants or risk factors are associated with each other. In that case, the effect of one is confounded with, or distorted by, the effect of the other. Confounding can occur because of selection bias, by chance, or because the two determinants are really associated in nature. Selection bias and confounding are not mutually exclusive, but they are often presented differently as they represent problems at different stages in a study. Selection bias is an issue when the sampling procedures for patients are determined during the design phase of a study, whereas confounding is an issue to consider during the analysis phase.

Often in the same study more than one bias operates, as in the following example. Imagine a study that compared the effect that surgical and nonsurgical management had on speech and language development in children with persistent otitis media with effusion. In this example, selection bias could have been present if the children who received surgical treatment came from a different background and had parents who were on average of higher socioeconomic status, or if they had a family history of chronic ear infection. Information bias could have occurred because the assessment of language development might have been influenced by the fact that those who were applying and interpreting the speech and language tests knew the treatment the children had received. Finally, the conclusion that surgical treatment improved speech and language development might have been the result of confounding if the children who received surgical treatment had had more serious or more frequent ear infections. The latter bias is often referred to as 'confounding by clinical indication'.

When designing studies, investigators should try as much as possible to rule out bias. The concerns about bias need to be thought through very carefully. This relates directly to the three components of a good research question, and these components should be represented adequately in the study design. First, the study sample should adequately represent the target population. Second, the measurement of the determinants should adequately represent the comparison of interest. Third, the measurements of the outcomes should adequately represent the outcome(s) of interest.

When confounding is anticipated, the investigator should consider design and analysis strategies to control its influence on the outcomes. The simplest approach in the design phase is restriction or specification. For example, investigators could decide to include only nonsmokers in a study on the effect of human papillomavirus and oropharyngeal cancer. The disadvantage of this strategy is that it reduces recruitment and prohibits generalization of the results to smokers. Another potential approach in the design phase is matching which means that subjects with matching

values for the confounding variables are included. This can be done individually (pair wise matching) or in groups (frequency matching). However, the use of matching has many disadvantages. The recruitment process can become rather cumbersome. Special analytical techniques are required that represent the fact that the subjects are not sampled independently. There is also the danger of overmatching – matching on the basis of a variable that is not a confounder, which would reduce the study's power. Given these disadvantages, matching should be avoided if other strategies could provide sufficient control for confounding.

In the analysis phase, the investigator can use either stratification or adjustment. Stratification ensures that the analysis compares like with like, first by comparing subjects within a group (or stratum) of subjects with similar values of one or more confounding variables and then, in a second step, by calculating an overall estimate by pooling the stratum-specific results. The most important disadvantage of this approach is the limited number of variables that can be controlled for. Adjustment on the basis of a statistical multivariate model does not suffer from this limitation, but its effects depend on the adequacy of the model fit. Both approaches depend on the completeness, precision and accuracy of the measurements of the confounders.

Observational studies

DESCRIPTIVE STUDIES

Descriptive studies can describe the experience in only one individual, a case report, or a report on a series of individual cases, the case-series report. Case series are the most frequently published studies in surgery. An important function of descriptive studies is that they can describe the distribution of diseases or disease-related conditions and events in a specified population.

Good descriptive research should address the five 'W' questions – who, what, why, when and where, although as soon as these questions are addressed on the basis of the data, the distinction between descriptive studies (no comparison) and analytical studies (comparison between groups essential) starts to disappear, but a distinctive characteristic of descriptive studies is that they cannot directly quantify the risk that can be attributed to a specific determinant. For example, a series of three cases was published recently of perichondritis of the pinna as a result of 'high' ear piercing, and was used to focus attention on the risks of body piercing.²² The study also presented the increasing trend in the number of hospital admissions for perichondritis of the pinna in the UK and Wales from approximately 600 in 1990–1991 to approximately 1200 in 1997–1998. The latter is an example of a surveillance study, which is another important type of descriptive study. A surveillance study is an ongoing and systematic collection, analysis and interpretation of health

data essential to the planning, implementation and evaluation of health services and public health practice. The fact that this particular descriptive study cannot quantify the attributable risk might not be a weakness as most cases of perichondritis of the pinna may be due to piercing practices in the first place.

The strength of descriptive studies is that they often use existing data and thus are inexpensive and efficient to carry out. Furthermore, few ethical limitations exist. The disadvantages are that there is a danger of over-interpretation. For example, in early 2001 the UK government recommended that single-use instruments should be used for adenotonsillectomy to minimize the risk of transmission of variant Creutzfeldt-Jacob disease (vCJD). In the course of the same year, suspicion was raised about the postoperative haemorrhage rate. It was thought that the increase in the haemorrhage rate was due to the poor quality of the single-use instruments and, in late 2001, the UK government recommended the reintroduction of reusable instruments. The need to consider alternative explanations arose later as more detailed analyses of hospital admission data revealed that there also had been a gradual increase in the post-tonsillectomy complication rate from 3.9 percent in 1995–1996 to 7.3 percent in 2000–2001 (unpublished data, Van der Meulen JHP, 2003).

Analytical studies

An important distinction that is often made with respect to observational studies that are analytical is whether the determinants and outcomes relate to phenomena that occur at the same time. If so, it is called a cross-sectional study. If not, it is either a cohort study (looking forward in time from determinant to outcome) or a case-control study (looking backward from outcome to determinant).

CROSS-SECTIONAL STUDIES

The single most important characteristic of cross-sectional studies is that the determinant(s) as well as the outcome(s) measured occur at the same time, and that there is no follow-up period. Cross-sectional designs are very well suited to describe the prevalence of health and disease-related conditions and their distribution patterns. For example, a study was carried out in 864 school children in the UK to investigate the effect of parental smoking on middle ear disease.²³ Data on parental smoking were collected with a questionnaire and glue-ear was considered to be present in children with a flat tympanogram. The study identified 82 cases in total, 45 in the 407 households with at least one smoker and 37 in the 457 households with no smokers, and a risk ratio of 1.4 (= 11.0 percent/8.1 percent, with a 95 percent confidence interval ranging from 0.9 to 2.1) could be calculated.

The major strengths of cross-sectional studies is that they examine the presence or absence of an outcome and determinant at the same time. Cross-sectional studies are therefore fast, relatively cheap, and there is no 'loss to follow-up'. A major disadvantage of cross-sectional studies is that they provide only a snap shot of complicated temporal relationships between determinant and outcome. Parental smoking, for example, is likely to be persistent, but chronic middle ear infection in children is an intermittent disease. As a consequence, causal relationships are difficult to establish with cross-sectional studies. For the same reasons, they are not suitable for producing information on prognosis or the natural history of a condition.

Studies of the accuracy of diagnostic tests are a special case of cross-sectional studies. A key feature of such studies is that the diagnostic test results and 'gold standard information' or reference test results about the presence or absence of the conditions of interest are collected at the same time. The subjects should have both undergone the diagnostic test in question (for example, ultrasound-guided fine-needle aspiration to diagnose malignant disease in patients with nodular thyroid disease), as well as the reference test (histology after surgical resection). The results of one test should not be available to those who are carrying out the other. In terms of the example, the pathologist examining the surgical specimen should be 'blind' to the results of the fine needle aspiration. Another important criterion for a valid evaluation of the diagnostic accuracy is that the diagnostic test is evaluated in 'an appropriate spectrum of patients' (such as those in whom we would use it in practice).

The accuracy of a diagnostic test, a measure of how well the test results help to distinguish between individuals with and individuals without the disease or target disorder, is often expressed in terms of sensitivity and specificity. However, it is important to realize that this is, in most cases, a simplified representation of the diagnostic accuracy. Sensitivity and specificity can only be calculated for a test with dichotomous results, often called 'positive' if the result suggests that the disease is present and 'negative' if it suggests that disease is absent. The sensitivity is estimated as the proportion of individuals with the disease who have a positive test result. The specificity corresponds to the proportion of individuals without the disease who have a negative test result. The sensitivity and specificity of a 'perfect' test are 100 percent. The sum of the sensitivity and specificity is sometimes used as a single measure of the diagnostic accuracy. The sum of the sensitivity and specificity for a 'worthless' test, a test that would perform no better than tossing a coin, is expected to be 100 percent and for a perfect test 200 percent.

In many cases, however, relying on sensitivity and specificity as measures of diagnostic accuracy is too simplistic. For example, many tests, if not all, have more

than two possible outcomes, and dichotomizing the results in a positive and a negative test result reduces the amount of diagnostic information that a test can provide. Furthermore, if one would like to dichotomize the test results, it is not immediately obvious what the cut-off value between positive and negative results should be. Lastly, the actual aim of performing a diagnostic test is not to distinguish between individuals with and without the disease, but to identify those individuals for whom the expected benefit of treatment outweighs the expected harm. This indicates that the classic diagnostic 'stepping-stone approach', jumping from signs and symptoms to diagnosis and then from diagnosis to treatment, is rather artificial in many cases. This should be reflected in studies assessing diagnostic tests. They should focus on clinical effectiveness (effect on patient outcomes) rather than on diagnostic accuracy alone (for a comprehensive review of methods for the evaluation of diagnostic technologies, see Knottnerus.²⁴)

COHORT STUDIES

Cohort studies follow groups of individuals over time. The word 'cohort' originates from the Latin word for a group of 300 to 600 soldiers in a Roman legion. This is appropriate as the same rule applies for epidemiological cohorts as once for Roman cohorts: if a person joins a cohort, he will be a member of that cohort forever, which emphasizes the need for the completeness of follow up. Most follow-up studies are analytical (comparing the occurrence of outcomes according to presence or absence of certain determinants), but they can be descriptive as well.

The design of many cohort studies is relatively straightforward. A group of people is assembled, none of whom have experienced the outcome of interest, but all of whom could experience it. On study entry, people may be classified according to the determinants of interest. These people are then observed over time to see in which of them the outcome of interest occurs. Despite this simple design, the terminology used to describe these studies can be confusing. For example, terms such as 'longitudinal study', 'prospective study' or 'incidence study' are often used interchangeably. The only real problematic issues in this respect is the use of the term 'prospective study', as cohort studies can consider data that are collected prospectively as well as retrospectively.

The terms 'retrospective' and 'prospective' refer to the way that the data have been collected rather than to the study design. The essential characteristic of prospective data collection is that data are being collected on determinants and outcomes that manifest themselves after the establishment of a study protocol. In all other situations, the data collection should be considered to be retrospective. Retrospective data collection can be based on data recorded in the past for other purposes or on the memory of the study subjects, investigators or other

parties. It is obvious that the precision and accuracy of prospectively collected data can be expected to be better than retrospectively collected data. Cohort studies can be based entirely on retrospective data (using retrospective data on both the determinants and the outcome), based entirely on prospective data (using prospective data on both the determinants and the outcome), or based on a mix of retrospective data on determinants and prospective data on the outcome.

Cohort studies have many attractive features. They are the best way of ascertaining the incidence of a disease or health-related event or condition, as well as the natural history of a disorder. They also provide insight into the temporal order of determinants and outcome, which strengthens the inferences that can be made about whether an observed risk factor is a cause of the outcome. Furthermore, multiple outcomes can be considered which is especially relevant if cohort studies are compared with case-control studies (see Case-control studies). However, the dangers of considering multiple outcomes are also obvious since testing many hypotheses may lead to misleading results. Lastly, prospective cohort studies are especially valuable for the study of fatal diseases, or more general studies of the occurrence of disease-related conditions with a short duration. When these kind of conditions are studied retrospectively, the observed occurrences may be an under-representation of all occurrences.

The major drawback of cohort studies is that they are relatively expensive and therefore an inefficient way to study rare outcomes. Cohort studies become more efficient as the outcomes become more common. Another disadvantage for cohort studies that collect outcome prospectively is that the results may not be available for a long time. A prospective study of the effect of passive smoking on the head and neck cancer incidence may take more than ten years to come up with relevant results.

However, not all prospective cohort studies need to take a very long time to complete. A cohort study could be used, for example, to study the risk factors for complications after tonsillectomy. Such a study could prospectively collect patient characteristics as well as data on surgical technique, instruments used and experience of the surgeons. Every patient could be followed up for a certain period, say one month, and the occurrence of complications could be registered. Such a study would provide insight into the incidence of complications – it might even distinguish between primary haemorrhage, secondary haemorrhage as well as infection, and also in the way this incidence depends on relevant risk factors.

CASE-CONTROL STUDIES

Case-control studies can be considered as 'research in reverse'.¹⁶ Many epidemiologists consider them as one of the most important tools in their armamentarium. The design of case-control studies can be appreciated by again

considering the example of the study on risk factors for complications after tonsillectomy. For this study, we could also use a case–control design. All the patients who experience a complication in the first month after surgery could be considered as ‘cases’, and patients without postoperative complications as ‘controls’. The investigators then have to look back in time to find data on the patient’s risk factors that were present at the time of surgery.

The essential feature of a case–control study is that not all controls need to be included but that a selection would suffice. Many case–control studies include only one control for each case, whereas others included more but hardly ever more than four or five. The reason that the number of included controls per case is seldom higher is that including more controls will have only a small effect on the power of the study and on the precision of the estimates (‘law of diminishing returns’). The fact that only information has to be collected for a selection of the controls makes that, in many circumstances, case–control studies are the most efficient design in terms of time, effort and therefore money. Hence, case–control studies are especially relevant if the occurrence of the outcome of interest is low. However, if the frequency of the determinant of interest is low, case–control studies might become inefficient. For example, if the frequency of a certain risk factor of post-tonsillectomy complications is low, investigators have to examine many cases and controls to find some who have been exposed. Some have advocated a ‘rule of thumb’ stating that cohorts are more efficient than case–control studies if the occurrence of the outcome is more frequent than that of the determinant and *vice versa*.

Unlike cohort studies, case–control studies cannot produce an estimate of the occurrence of the outcome of interest since we lack information about the denominator. A case–control study of post-tonsillectomy complications will neither provide information on how many patients underwent the operation nor on what their risk factors were. The relevant effect measure that a case–control study can provide is the odds ratio for a determinant, derived from the proportions in cases and in controls (more precisely, the odds) in whom the determinant is present. Earlier, we referred to this odds ratio as the ‘determinant odds ratio’. This determinant odds ratio is equivalent to the ‘outcome odds ratio’ and the odds ratio obtained from a case–control study can therefore be used as a measure of relative risk.

The advantage of case–control studies (efficiency in time, effort and money) comes at a price however, because two methodological issues may introduce major systematic errors: selecting the control group and obtaining information about the determinants. The selection of cases is relatively straightforward provided that the definition of the outcome being studied (the ‘case definition’) is clear. The selection of the control group is more problematic. Two criteria need to be met. First,

controls should be representative of the population at risk of becoming cases. In other words, the controls should have been selected as cases had they developed the disease or outcome of interest themselves. Second, selection of the cases should be independent of the determinant(s) being investigated. Therefore, a case–control study of risk factors for post-tonsillectomy haemorrhage should include as controls only patients who underwent a tonsillectomy themselves. Furthermore, it seems inappropriate to select as controls all patients who underwent a tonsillectomy immediately after patients who developed complications. If that were the case, it would be very likely that the same surgeon using the same technique and the same type of instruments treated these patients. It is left as an exercise for the reader to decide what an appropriate strategy to select controls would be.

RANDOMIZED CONTROLLED TRIALS

Randomized controlled trials are cohort studies with prospective data collection. Their distinctive feature is that they use a random allocation scheme to assign the determinant. With randomization, you can expect that the prognostic characteristics of the randomized groups or ‘arms’ of the trial are similar except for differences due to chance variation. Randomization eliminates the influence of both known and unknown confounders that are present at the time of randomization. Without randomized treatment allocation, it cannot be excluded and is in practice very likely that imbalances in prognostic factors between the groups occur that are the result of selection bias – a type of bias often called ‘confounding by clinical indication’.

The ethical argument in favour of a random process deciding what intervention patients receive is that there is equipoise, or a state of genuine uncertainty on the part of the clinical investigator regarding the comparative merits of each intervention. If there is genuine uncertainty about which treatment is best, it is not possible to recommend one over the other which justifies that a random process decides. The problem is, however, that equipoise depends on subjective judgements and that therefore experts may disagree. Furthermore, preferences of patients or those who are candidates to receive the intervention have to be taken into account. The process of informed consent should address all these issues to ensure that patients can evaluate the potential risks and benefits of the study from their own perspective before they agree to participate.

It is important that the randomization process is ‘concealed’ from the investigators who include the participants into the trial. Proper allocation concealment requires that the investigators do not know the arm to which a participant will be allocated until the participant has definitively been recruited and included in the study. Concealment of the randomization is the only way to prevent the investigators influencing the balance of the

prognostic characteristics between the groups that are being compared. For example, prior knowledge of the next allocation may allow investigators to exclude certain candidate participants from the trial because they are perceived to be allocated to an inappropriate group. More directly, the investigators may try to influence the order of inclusion. Concealment of treatment allocation is so important that with inadequate concealment a randomized controlled trial should be considered nonrandomized. Empirical studies have shown that trials with inadequate concealment overestimate the treatment effect by as much as 40 percent on average.

Another important feature of many randomized controlled trials is the use of a form of blinding, which prevents the participants and the investigators who are in contact with the participants from being aware of which treatment has been offered. Blinding can help to prevent bias in a number of ways. First, if participants do not know what treatment they are receiving, it is less likely that their perceptions and expectations of the treatment that they receive can influence their compliance and the physical and psychological response to the intervention. For example, most patients expect that a new treatment is better than an existing one. Second, blinding investigators is important, as this would prevent them consciously or unconsciously managing the participants in the trials differently. Also, their attitude towards the treatment can influence how patients respond to the treatment. Third, blinding participants and investigators will prevent outcomes from being assessed differently. The terms 'single-blind' and 'double-blind' are often used to indicate trials in which only the participants or both the participants and the investigators are blinded.

Double blinding is impossible in almost all surgical trials. To avoid biased management, the investigators should then try to standardize other potential treatments as much as possible. Approaches to minimize biased assessment of outcomes could include the use of a third party who is unaware of the treatment originally given. When blinded assessment is not possible, one should try as much as possible to use 'hard outcomes' (based on measurements resistant to bias). Another alternative includes the use of standardized outcome measurement scales that can be completed by the participant. This approach is likely to produce less biased outcomes than the judgement of an investigator.

Many people also consider the use of a placebo treatment as an essential feature of a randomized controlled trial. Placebo treatment is a form of treatment indistinguishable from the 'active treatment' under study, but it does not have a specific known mechanism to influence a patient's health. Blinding often requires the use of placebo treatment. Apart from that, the choice whether to use placebo treatment depends on the question that the trial tries to answer. First, if the question is whether intervention A is better than intervention B, then it is obvious that one should compare the effects of

A and B with each other and not against placebo treatment. Second, if the question is whether intervention A is better than no treatment at all, the answers may be different for researchers and clinicians. Researchers are likely to be more interested in the specific effects – effects that can be attributed to the 'active component' of an intervention. Clinicians are likely to be more interested in the combined effects of the active and placebo components. On the other hand, it is always useful to know what part of the total effect is due to the active component and what part to the placebo when balancing the potential benefits against potential harms and costs, which are likely to differ between the active and placebo components. It is obvious that placebo treatment is rarely an option for randomized controlled trials in surgery. For example, in a trial comparing tonsillectomy with nonsurgical management, it would require a form of 'sham surgery' to provide a placebo treatment. It is left to the reader to decide what the advantages and disadvantages of using such a form of placebo treatment in this context would be.

If a substantial number of participants do not receive the study interventions, do not comply with the study protocol or are lost to follow up, the trial is likely to be underpowered and its results biased. Strategies to maximize compliance and follow up should therefore be an integral part of every trial protocol. An obvious strategy is to make participation in a trial as convenient, painless and enjoyable as possible. Some trials have a 'run-in period' that can be used to 'screen out' patients who may not adhere to the study protocol and the follow-up procedures. It is essential to ascertain that compliance and completeness of follow up do not differ between the trial arms as this could lead to biased estimates of the effects of the interventions.

The results of trials can be analysed in two ways. First, the comparison of the intervention can be carried out according to the intervention to which the patients were randomized ('intention-to-treat' analysis) or according to the treatment they actually received ('per protocol' analysis). The advantage of an intention-to-treat analysis is that the question that is being addressed corresponds exactly with the one clinicians and patients try to answer in clinical practice. The disadvantage is that if many patients do not receive the treatment they were randomized to, this would obscure the difference between the trial arms. Per protocol analysis, on the other hand, addresses which intervention is better more directly. With this form of analysis, the treatments are being compared according to the treatments that the patients actually received. The problem with this approach is that if many patients do not receive the treatment to which they were randomized, the study no longer represents an experimental study.

The analysis should focus on a single outcome – often referred to as the 'primary endpoint' – to avoid the problems of interpreting the outcome of multiple

hypothesis tests. This primary endpoint should also be used for the power calculation in the design phase of the trial. It is often desirable to consider a number of secondary endpoints – outcomes that represent different aspects of the outcome of interest – to provide a more detailed picture of the effects of the interventions under study. For example, a randomized controlled trial of tonsillectomy and nonsurgical management could consider the reduction in the number of episodes of tonsillitis or sore throat as primary endpoint, but could also collect information on postoperative complications, reduction in time off work and reduction in the use of certain drugs, such as analgesics and antibiotics.

Subgroup analyses are comparisons between randomized groups in a subset of the patients with specific characteristics. The most important question that subgroup analyses try to answer is whether the effect measure is different in different subgroups by carrying out a statistical test for interaction (or ‘effect modification’). For example, one could investigate – when analysing the results of the trial on tonsillectomy – whether the effects of tonsillectomy on recurrence of tonsillitis are different in children younger than five years compared to children of five years and older.

Subgroup analyses can be dangerous and misleading, but they can also provide an important extra insight into the generalizability of the results. One danger arises from the fact that multiple comparisons are carried out, which increases the risk of producing false-positive results. To avoid this risk, only a limited number of subgroup analyses should be carried out and they should be specified in the study protocol, in other words, before the results of the trial are known and on the basis of patients characteristics that are measured before randomization. Furthermore, the actual number of subgroup analyses carried out should be reported. Another approach to minimize the risk of false-positive results is to reduce the significance level of the statistical tests for interaction (for example, from the conventional 0.05 to 0.05 divided by the number of tests carried out as specified by the Bonferroni method). A further danger is the limited power of the subgroup analyses, because the group size is, by definition, smaller than that of the original trial population.

An important problem of randomized controlled trials is that of generalizability. Most trials are carried out in highly controlled conditions in a selected group of patients. Their results therefore provide evidence about the efficacy of an intervention (does the treatment work under ideal circumstances?) and not about the effectiveness (does the treatment work in actual practice?). It depends on the question that needs to be answered as to what extent the design of a trial should focus on efficacy or on effectiveness. An explanatory trial (addressing the efficacy question) is needed in the early stage of a new intervention. However, a pragmatic trial (addressing the effectiveness question that aims to create study conditions

that reflect as much as possible actual practice when effectiveness is more important) is more appropriate to answer whether an intervention should be included in the ‘repertoire’ of available services.

It is obvious that not all questions about the effectiveness of surgical procedures can be addressed with a randomized controlled trial.²⁵ A number of obstacles have been identified that make randomized controlled trials inappropriate (outcome of interest relatively rare, relevant outcomes far in the future, or randomization affecting the effectiveness of a procedure), impossible (refusal of clinicians or patients to participate, ethical obstacles), or inadequate (low generalizability of experimental studies).²⁶ If the obstacles are insurmountable, carefully designed observational studies should be considered.

Concluding remarks

This chapter introduces the ‘determinant–occurrence relationship’ as a key concept for medical research, and epidemiology as a methodological discipline with immediate relevance for otolaryngological research. A basic understanding of epidemiological principles is therefore essential for all people who are involved in clinical research and desirable for all clinicians who want to read the medical literature critically.

We have only presented a broad picture of epidemiological concepts and principles, but it will be clear to the reader that studies vary according to the likelihood that their results are accurate (free of systematic error) and precise (random error). For this reason, a ‘hierarchy of evidence’ has been suggested.¹¹ For therapeutic issues, this hierarchy ranges from well-conducted randomized controlled trials at the top – preferably summarized in a systematic review and meta-analysis – to case-reports and expert opinion at the bottom (used throughout this book). For diagnostic and prognostic issues, very different hierarchies are necessary. These hierarchies of evidence are not absolute. If the therapeutic effects are very large in comparison to the potential effects of bias – for example, effects of insulin in ketoacidosis – a description of a series of cases may already provide compelling evidence. Nevertheless, it should be a leading principle that users of research try to look for the best available evidence from this hierarchy.

KEY POINTS

- Epidemiology is a methodological discipline. Epidemiological concepts and principles will help to design empirical studies that are relatively precise (free of random error), accurate (free of systematic error or bias) and

efficient (affordable in terms of time and money).

- The 'determinant–occurrence relationship' is a key epidemiological concept, and many clinical research questions can be 'framed' as determinant–occurrence relationships.
- Epidemiological studies can be distinguished into experimental studies (investigators assign the determinants themselves, e.g. randomized controlled trial) and observational studies (investigators examine events as nature takes its course). Observational studies without a comparison or control group are called descriptive studies.
- A research protocol is a document that provides all essential details of a study. It should contain information on:
 - research question;
 - study design;
 - selection and recruitment of the subjects;
 - measurements;
 - statistical analysis;
 - sample size calculation.

A 'hierarchy of evidence' has been suggested on the basis of the likelihood that results are accurate and precise. For therapeutic issues, this hierarchy ranges from well-conducted randomized controlled trials at the top – preferably summarized in a systematic review and meta-analysis – to case-reports at the bottom.

SEARCH STRATEGY

The aim of this chapter is to explain the background to patient-based outcomes research. There is a vast literature on this subject, so there was no formal literature search. The emphasis is on instruments relevant to otolaryngology. The instruments described are simply examples for the reader. The author does not suggest that these are the best instruments in their subject area.

INTRODUCTION

Clinical outcomes research examines the outcomes of treatment or of disease. Traditionally, outcomes of medical care are based on clinical observations or laboratory measurements. While these measures provide useful information for the clinician, they are often of limited interest to patients. There is often poor correlation between clinical outcomes and functional capacity and well-being which are the areas of most interest to the patient. There has been increasing recognition that traditional measures need to be complemented by some measure reflecting the impact of the intervention on the patient in terms of health status and health-related quality of life. These terms refer to experiences of illness such as pain, fatigue, disability and broader aspects of the individual's physical, emotional and social well-being. Medicine, in particular surgery, formerly had the principal objective of reducing mortality and morbidity. These objectives are usually straightforward to assess.

Nowadays, a large proportion of clinical practice is either cancer or chronic disease. There has been little improvement for some time in survival in cancer while treatments often have associated side effects and functional impairment which significantly affect the patient's quality of life. There is an increasing prevalence of chronic diseases with an ageing society and here the aims of treatment are to arrest or reverse decline in function.¹ These factors have led to an increased interest in patient-based outcome measures.

At the same time, increased attention is being given to patients' opinions and wishes in relation to their health. Patients should be involved in decisions about their treatment. To contribute usefully, they need information about the outcomes of treatment, not just in terms of surgical results but in terms of the possible effects on their quality of life. Financial resources limit health care around the world, and increasingly the distribution of these resources is influenced by the benefits perceived by patients, their carers and society as a whole.

WHAT ARE PATIENT-BASED OUTCOME MEASURES?

Patient-based outcome measures are, in general, questionnaires that ask patients about their perception of their health. Usually, these instruments are made up of a number of items or questions. These items are linked in a number of domains or dimensions. A domain refers to an area of behaviour or experience, such as mobility, self-care, depression, pain, social functioning and general well-being. Many questionnaires focus on physical function, such as ability to walk, climb stairs, wash and dress themselves. Others ask about the impact of health on various areas of an individual's life, such as ability to socialize with members of their family and friends. These are aspects of health-related quality of life (HRQoL). Overall quality of life is influenced by many factors other than health, such as social, financial and physical factors. Patient-based outcome measures assess only one aspect of quality of life and are not measures of overall quality of life.

Patient-based outcome measures assess some aspect of the patient's subjective experience of health and the consequences of illness – and of treatment. As these experiences are those of an individual patient with an individual personality and lifestyle, they cannot be objectively verified. This point is sometimes raised as a criticism of patient-based outcome measures, but it should be borne in mind that many clinician-based outcomes are the subjective opinion of the clinician.

WHY USE PATIENT-BASED OUTCOME MEASURES IN RESEARCH?

In the early days of research, few if any studies included an assessment of health-related quality of life. It is increasingly argued now that clinical trials should include patient-based outcome measures except where it is clear that these are not relevant outcomes. The UK Medical Research Council (MRC), the European Organisation for Research and Treatment of Cancer (EORTC) and the National Cancer Institute of Canada (NCIC) all have policies stating that the likely impact on quality of life should be assessed, or justification provided for not doing so.² Patient-based outcome measures have been used as the primary outcome measure in randomized controlled trials in many areas including cancer and heart disease. They are also useful in providing evidence of the overall value of a treatment in a way that allows comparison with other treatments in the same area or in other areas.

Patient-based outcome measures are particularly relevant in otolaryngology. Head and neck cancer forms a small proportion of our patients, but a much larger proportion of our clinical workload. The majority of our patients do not have a life-threatening condition and the morbidity is small. Most of our patients simply want us to make them feel better. In many cases we do not have

reliable, objective clinical measures to assess the outcome of treatment. To justify our treatment we need patient-based outcome measures to demonstrate the efficacy of treatment – improvement in HRQoL. We also need patient-based outcome measures to demonstrate the effects of these non-life-threatening conditions on HRQoL.

Even when we have objective measures, e.g. closure of a tympanic membrane in myringoplasty, we often know little about the effects on HRQoL. There are also occasions where there is disagreement between clinical measures of success and HRQoL outcomes, e.g. septal surgery for deviated nasal septums. It is likely that the results from one of the measures are unreliable or that they are measuring different things – the validity of both measures should be questioned.

ASSESSMENT OF PATIENT-BASED OUTCOME MEASURES

There are eight criteria that should be applied to patient-based outcome measures: appropriateness, validity, reliability, responsiveness, precision, interpretability, acceptability and feasibility³ (Table 50.1). There are few patient-based outcome measures for which there is sufficient evidence to allow judgement on all of these criteria.

Appropriateness

The first and most fundamental question when selecting a patient-based outcome measure is how to identify one

Table 50.1 Assessment of patient-based outcome measures.

Criterion	Meaning
Appropriateness	Does the content of the instrument match the intended purpose of the trial?
Validity	Does the instrument measure what it claims to measure?
Reliability	Does the instrument produce the same results when repeated in the same population?
Responsiveness	Does the measure detect clinically meaningful changes in the patient condition?
Precision	Can the instrument detect small differences between patient groups?
Interpretability	Can results from the measure be interpreted clinically and are they relevant?
Acceptability	Is the format of the instrument and the questions acceptable to the planned subjects?
Feasibility	Is it feasible to use this instrument in this setting with these subjects?

that is appropriate to the aims of the particular trial. The aims of the trial, the patient group being studied, the type of treatment and the relevant quality of life questions should be carefully considered. The instrument should measure aspects of patients' lives that patients consider important, and should not omit aspects of HRQoL that are important to the patients in the trial.⁴ Clinicians often think that they know what aspects of HRQoL are important to patients. Many studies have demonstrated, however, that patients' views often differ from clinicians'. The most effective way of establishing the importance to patients is asking patients their views. A list of aspects of HRQoL can be drawn up by clinicians and patients. A group of patients can then be asked which of these items are problems for them and how important these items are. This is the method commonly used in creating the patient-based outcome measures which are widely used, such as the Medical Outcome Study Short-Form 36-Item Health Survey (SF-36).

The purpose of the trial must be specified precisely in order to select an instrument that fits that purpose. In many studies, the rationale for selection of outcome measures is not clear. Careful consideration of content and relevance of a questionnaire to the purpose of the trial should be given. The instrument selected must be as relevant to the health problem and the proposed intervention as possible.

It is often recommended that one generic and one disease-specific instrument be used in a trial to increase the likelihood of appropriate assessment of outcomes.

Validity

The validity of a measure is an assessment of the extent to which it measures what it claims to measure. Validity is not a fixed property of a measure, but is assessed in relation to a specific purpose and setting.⁵ It is, therefore, meaningless to refer to a validated outcome measure, as many reports do. Evidence of validity of an outcome measure in one situation does not mean that there will be adequate validity in another research setting.

This apparently simple property depends on a range of different types of evidence, including how the content was chosen and its relationship to other variables. There are several different ways of assessing validity of a patient-based outcome measure. No single set of observations is likely to determine validity, so assessment of validity in relation to a specific trial is not straightforward.

CRITERION VALIDITY

Criterion validity is the correlation of a measure with an objective or 'gold standard' measure. As gold standard measures rarely exist in assessment of quality of life, criterion validity is rarely relevant in patient-based

outcome measures, and validity is judged by a more indirect assessment of content and construct validity. It can be assessed when a shorter version of an instrument is used to predict the results of a full-length version.

FACE AND CONTENT VALIDITY

Face and content validity are among the most relevant issues for the use of patient-based outcome measures in clinical trials. They address whether items clearly address the intended subject matter and whether the range of aspects is adequately covered. They are explained by Guyatt *et al.*⁶ 'Face validity examines whether an instrument appears to be measuring what it is intended to measure, and content validity examines the extent to which the domain of interest is comprehensively sampled by the items or questions in the instrument.' In other words, does the questionnaire look right and does it cover the right things? Face and content validity are mainly based on careful examination of the content of the instrument and qualitative judgement rather than statistical criteria. Evidence of how the questionnaire was initially developed is useful. Questionnaires with good validity are constructed in phases with involvement of patients with experience of the particular health problem. The content of poor questionnaires is chosen by 'experts'.

CONSTRUCT VALIDITY

Construct validity is also very relevant but is a quantitative assessment of the relationship of a construct to other variables. A construct is a theoretical idea about the domain to be measured. For example, patients with hearing disability should have poorer audiometric thresholds. Many patient-based outcome measures are multidimensional: they assess, for example, physical, psychological and social aspects of an illness. Those questions related to psychological aspects should correlate with each other much more than with questions assessing physical function. The internal structure of such instruments is established by construct validation, most commonly factor analysis. For a detailed discussion of assessment of construct validity, the reader is referred to Fitzpatrick *et al.*³

Reliability

Reliability is the reproducibility and internal consistency of an instrument. It assesses the extent to which the instrument is free from random error. It is essential to establish that any changes observed in a trial are due to the treatment and not to problems in the measuring instrument. As the random error increases, the size of the sample required to produce an accurate result increases.

REPRODUCIBILITY

Reproducibility is the degree to which an instrument gives the same results on repeated applications with the same subjects, and is also known as the test–retest reliability. An instrument should produce the same, or very similar, results on two or more administrations. This should be relatively straightforward to assess, but care must be taken with the time interval between tests. Repeat measurements should be far enough apart in time for the subject to forget their earlier answers, but not so far apart that their health status might have changed. This is commonly reported as a correlation coefficient. However, a correlation coefficient measures the strength of association between two measures and not the extent of agreement.⁷ Bland and Altman⁷ recommend plotting the scores from the two tests graphically which is certainly a simpler method than a statistical comparison of repeated scores.

INTERNAL CONSISTENCY

More than one question is usually used to measure one domain in a questionnaire because several related observations will produce a more reliable estimate than one. Individual questions in a domain should correlate highly with each other and with the total score for questions in that domain. This is the internal consistency of a patient-based outcome measure. The correlation is often measured using Cronbach's alpha.^{8,9} If all the questions in a domain are the same, Cronbach's alpha will be 1, while if there is no relationship alpha will be 0. If the correlation is too high, it is likely that the questions are addressing a very narrow aspect of an attribute and some items may be redundant which then reduces the content validity. It is therefore suggested that Cronbach's alpha should be between 0.7 and 0.9.¹⁰

Responsiveness to change

Responsiveness is the ability of an instrument to detect clinically important change, even if that change is small.¹¹ This is sometimes called sensitivity to change but the term sensitivity has other, more general uses. It is particularly important in clinical trials when changes might correspond to therapeutic effects of treatment. An instrument can be both reliable and valid but not responsive to change.

There are several statistical methods of assessing responsiveness. The simplest method is to compare change scores for an instrument over time with changes in another variable or variables. The other variable should preferably be an objective indicator, such as a physiological measurement or a clinician-based outcome measure.

An alternative method of assessing responsiveness is calculation of the effect size in a given clinical situation. This is the size of change in a measure between

assessments, for example before and after treatment, compared with the variability of scores for that measure on one assessment. The effect size is defined as the mean change in a variable divided by the standard deviation of that variable.¹² [**/*] The effect size can then be expressed in standardized units that allow comparisons with other outcome measures. It has been suggested that effect sizes can be used to assess the size of change in a study arm: an effect size of 0.2 is small, 0.5 is medium and 0.8 or greater is a large change.¹² [**/*]

Other more complex statistical measures of responsiveness are described by Fitzpatrick *et al.*³

One of the main limitations on the responsiveness of an instrument is when the wording of questions does not allow reporting of very good or very poor health states: ceiling and floor effects. Subjects with initial high scores may not show any improvement following effective treatment and those with initial poor scores may not show any deterioration when their clinical situation deteriorates.

As with validity, evidence of responsiveness in one situation does not mean that there will be adequate responsiveness in another research setting.

Precision or sensitivity

The preferred term is precision as sensitivity has a number of other uses in research. Precision is the ability of the instrument to reflect true differences in health states. As clinical trials often aim to detect small differences between patient groups, precision is a desirable capability.

One of the main influences on the precision of an instrument is the format of the answers. The simplest answers are 'yes' or 'no', but they do not allow any assessment of difficulty or severity. The most commonly used graded response is a Likert scale, such as:

1. very satisfied;
2. satisfied;
3. neither satisfied or dissatisfied;
4. dissatisfied;
5. very dissatisfied.

There is some evidence that using seven response categories rather than five increases precision, though this is rarely used.

The main alternative to a Likert scale is a visual analogue scale, where patients can mark any point on a line to represent their answer. Though this would appear to offer more precision, comparison studies of Likert scales and visual analogue scales have found no advantage of visual analogue scales. In addition, it appears that visual analogue scales are less acceptable to many patients who find it difficult to translate their feelings into numbers.

Patients' responses in patient-based outcome measures are generally converted into numerical values for

statistical analysis. Most instruments use simple ordinal values, for example one to five (or seven) for a Likert scale, which are capable of less precision. However, the majority of published reports of health status measures use parametric statistical analysis that is appropriate for interval scales,¹³ though the interval between one and two (very satisfied and satisfied) may not be the same as between four and five (dissatisfied and very dissatisfied).

Some patient-based outcome measures use an explicitly derived weighting system for responses. The weights can be assigned by a panel of patients and health professionals, for example the Nottingham Health Profile,¹⁴ or be based on preference measurements obtained from a random sample of the general population, such as the Health Utilities Index (HUI).^{15, 16} The fact that weighted scoring systems appear to be much more exact with their scoring suggests that they might be more precise, but this may well be deceptive. Several studies have compared weighted and ordinal scoring systems and have not shown any significant difference in precision between these two methods of scoring.

Ceiling and floor effects may influence scores of instruments. Some patient-based outcome measures do not include questions that would identify very poor levels of health, so all patients with poor health have similar scores and further deterioration will not be identified. Sometimes patients with minor health problems will be scored as having excellent health so treatment of their problem will not result in any improvement in score.

One other important factor in precision is bias. This can be reduced by general aspects of study design, such as making assessments blind to intervention. In many cases it is not possible to keep the patient blind to which treatment arm of a trial he is in, so his judgement of outcomes may be influenced.

Patient-based outcome measures may therefore vary in how precisely their scores relate to underlying distributions of patients' health status. Researchers need to carefully consider factors that might influence precision. The degree of precision required of a patient-based outcome measure will depend on other aspects of trial design such as sample size and the expected differences between arms of the trial.

Interpretability

Can results from the measure be interpreted clinically and are they relevant? The interpretability of an instrument is concerned with how meaningful are the baseline scores or a change in scores. Clinically important changes in scores can be estimated by comparison with clinical or laboratory tests in the same patient group. Representative data are available from the general population for some widely used instruments such as the HUI (see under Utility measures) and the SF-36. The scores from the trial patients can be compared with the means and standard

deviations for the general population. A significant change in the score in the trial could be set at one and a half standard deviations from the population mean.¹⁰

Acceptability

Clearly it is essential that the format of the instrument and the questions are acceptable to patients. An instrument should not cause distress to patients or be difficult to understand. In general, shorter instruments are more acceptable to patients. The instructions to patients should make it very clear that their answers will not influence their treatment. Acceptability is also important in order to obtain high response rates to questionnaires to make results of trials easier to interpret, more generalizable and less prone to bias due to nonresponse. When choosing an instrument, it is useful to know if the instrument has been used in similar settings before.

Ideally, acceptability of an instrument should be directly tested at the design stage by seeking the views of patients. Subsequently, evidence of acceptability can be found in patient response rates.

Feasibility

The feasibility of an instrument is dependent on the time available for its completion and the staff available to help with its completion, either by interviewing patients or explaining the instrument to patients. The data collected have to be entered onto a computer and the time required and ease of entering has to be considered. The measure must be short enough to be completed or administered in the intended setting and with the types of patients and families involved in the trial. This is one of the criteria of patient-based outcome measures that can usually be easily judged by investigators in the research setting. If in doubt, feasibility can be assessed by piloting the study methods.

TYPES OF PATIENT-BASED OUTCOME MEASURE

There are two basic types of patient-based outcome measures: generic and specific. Generic instruments access multidimensional health profiles, overall medical condition and personal function. Specific instruments focus on the problems found in individual diseases, disabilities and patient groups.¹¹ Within each of these categories there are different types of instruments (Table 50.2).

GENERIC INSTRUMENTS

Generic instruments are designed to access a broad range of aspects of health status and the consequences of illness

Table 50.2 Types of patient-based outcome measures.

Category	Type	Example
Generic	Health profile	SF-36, Sickness Impact Profile, Nottingham Health Profile, Glasgow Benefit Inventory
	Utility	Health Utilities Index (HUI), EQ-5D
Specific	Disease specific	Dizziness Handicap Inventory (DHI)
	Site specific	Sino-Nasal Outcome Test (SNOT-20)
	Dimension specific	McGill Pain Questionnaire

and therefore to be relevant to a wide range of patient groups and conditions. The advantage of generic instruments is that they can be used for a broad range of health problems and this enables comparisons across different groups of patients with diverse conditions. Because of their broad range of content and general applicability, such instruments have been used to assess the health of samples from the general population. Such data have been used to generate normative values across populations with which other groups of patients with specific health problems can be compared. Since generic instruments are used more often than specific instruments, there are usually more data available regarding their reliability and validity.

As generic questionnaires cover a broad range of aspects of health status, many items may be irrelevant to a particular condition. These items result in a wide range of scores which are not relevant to the condition being studied. As there are few questions relevant to a specific condition, the instrument may be insensitive to changes that might occur as a result of treatment for that condition.

Health profile

SF-36

The most commonly used health profile instrument is the SF-36.^{17, 18} [**] The SF-36 is a 36-item, self-completed questionnaire which measures health status in eight dimensions: physical functioning, role limitations due to physical problems, role limitations due to emotional problems, social functioning, mental health, energy and vitality, pain and general perceptions of health. It can be completed by the patient in less than ten minutes. Responses are summed to give a score for each dimension: physical component summary (PCS) and mental component summary (MCS).¹⁹ It has been used in a wide variety of patient groups and conditions, including many otorhinolaryngological conditions (Table 50.3). Data from trial subjects can be compared with normative data for the population.²⁸ Garratt *et al.*²⁹ identified 408 papers

Table 50.3 Examples of the use of the SF-36 in otolaryngology.

ORL condition	Reference
Chronic rhinosinusitis	van Agthoven <i>et al.</i> , ²⁰ Gliklich and Metson, ²¹ Piccirillo <i>et al.</i> ²² [***/**]
Chronic otitis media	Nadol <i>et al.</i> ²³ [**]
Dysphonia	MacKenzie <i>et al.</i> ²⁴ [****]
Laryngeal cancer	Stewart <i>et al.</i> ²⁵ [**]
Meniere's disease	Smith and Pyle ²⁶ [**]
Rhinoplasty and otoplasty	Klassen <i>et al.</i> ²⁷ [**]

which included aspects of development and evaluation of the SF-36 over a ten-year period (1990–1999). It can also be used in a reduced 12-item version which is a subset of the original SF-36.³⁰ [***] However, the larger instrument gives more reliable estimates of individual levels of health and is therefore the better choice of instrument in small studies.

Recently, Brazier *et al.*³¹ derived from the SF-36 a preference-based single index measure, the SF-6D, to make the instrument more useful in evaluations of cost-effectiveness (see Utility measures below and in Table 50.3). This weighted scoring model could potentially be applied to any SF-36 data set. However, initial validation studies demonstrated some inconsistencies and further assessment of the scoring model is required.³² [**]

SICKNESS IMPACT PROFILE

The Sickness Impact Profile (SIP) is a general health-status questionnaire comprising 136 questions answered as either 'yes' or 'no'.³³ [***] They are grouped into twelve categories: walking, body care and movement, mobility, social interaction, alertness behaviour, emotional behaviour, communication, sleep and rest, eating, home management, recreational activities and work. Each item is weighted, and the scores of all answered questions are combined. There are twelve category scores, two summary scores (physical and psychosocial) and a total score. The scores are standardized and range from 0 to 100 points, with 100 indicating the poorest function. The test–retest reliability and internal consistency are high and it has good content and construct validity.³³ [***] It is, however, a long questionnaire and is usually administered by interview. Its acceptability and feasibility in a trial must be carefully considered.

NOTTINGHAM HEALTH PROFILE

The Nottingham Health Profile is a generic, self-administered questionnaire designed to measure perceived physical, social and emotional health problems.^{14, 34} An initial pool of statements was collected from patients at interview and from this pool 38 items were chosen

relating to six dimensions: physical mobility, pain, social isolation, emotional reaction, energy and sleep. The scores can be compared with the average scores in a population matched for gender and age.

GLASGOW BENEFIT INVENTORY

As other generic instruments are often insensitive to the nonacute disorders generally seen in an ORL clinic, the Glasgow Benefit Inventory (GBI) was developed for use in patients with otolaryngological conditions.³⁵ [**] The GBI is a post-intervention questionnaire that assesses the effects of interventions on the health status of patient, rather than the actual health status. The GBI has 18 items in three domains: psychological, social and physical well-being. Rather than attempt to assess the difference between before and after treatment measures, it asks directly about the change in health status resulting from treatment. It is likely, therefore, to be more sensitive to such change than two separate instruments before and after intervention. In addition, compliance will be significantly higher because patients are only required to complete one questionnaire. The response to each question is based on a five-point Likert scale, for example: 'Since your *operation/intervention*, have you found it easier or harder to deal with company?' The words in italics (*operation/intervention*) in each question are replaced by words appropriate to the intervention of interest. Responses are scored using a weighted scale from a population sample to give a score between -100 and +100.

The GBI has been used to assess the benefit experienced by patients following various treatments (Table 50.4). Details of the questionnaire and its use can be found at www.ihr.gla.ac.uk.

Utility measures

Multi-attribute utility measures access a broad range of aspects of health status, like other generic instruments, but have a particular form of numerical weighting or valuation of health states. Utility measures have been developed from economics and decision theory in order to provide an estimate of individual patients' overall

preferences for different health states. They are scored as a single number between 1 (full health) and 0 (death). The weighted scoring method is based on preference measurements obtained from samples of a general population. They are asked to value different aspects of health as defined by the instrument using one of a number of valuation techniques, most commonly standard gamble, time trade off and visual analogue scales (see Brazier *et al.*,⁴² for explanation).

Utility scores reflect the health status and value of that health status to the patient. As utility measures are scored as a single value, they do not define individual dimensions of health that contribute to the individual's overall sense of well-being. They are relatively insensitive to small but relevant changes in health and are therefore more suited to studies of large populations.

There are several health utility measures that have been widely used. Brazier *et al.*⁴² carried out an extensive review of these and recommended the HUI and the EuroQol (EQ-5D) as the instruments of choice.

HUI

The HUI-I evolved from studies in neonatal intensive care.⁴³ [**] A second version (HUI-II) was developed to assess outcomes in long-term survivors of childhood cancer, but is suitable for use in a wider range of children.¹⁵ Though it is claimed to be a generic instrument, its content is explicitly aimed at children with questions specifically aimed at developmental age.

The HUI-II was revised to make it more relevant to an adult population. The HUI-III assesses nine aspects of health status: vision, hearing, speech, ambulation, dexterity, emotion, cognition, self-care and pain.⁴⁴ It has 15 questions with four to six available responses for each and is easy for patients to complete. The HUI-III has been used in a wide variety of clinical studies and has been shown to be reliable and responsive.⁴⁵ It is one of the few generic patient-based outcome measures which specifically assesses hearing and speech and is therefore potentially useful in many areas of otolaryngology. Normative data have been collected from large populations and, from these data, weighted scoring scales have been devised.¹⁶ It has been used in a cost-utility study of cochlear implants⁴⁶ and in the UK cochlear implant study.⁴⁷ [***]

EQ-5D

The EQ-5D is a self-completed questionnaire with five dimensions: mobility, self-care, usual activities, pain/discomfort and anxiety/depression.⁴⁸ It is easy to complete and is very acceptable to patients. Responses can be scored using a weighted scale from a large general population sample.⁴⁹ It is very brief with only five questions with three levels of response for each. Brazier *et al.*⁴² compared the EQ-5D and the SF-36 in a survey of 1980 adults and found the EQ-5D to be less sensitive.

Table 50.4 Examples of the use of the GBI.

ORL intervention	Reference
Bone-anchored hearing aids	Dutt <i>et al.</i> ³⁶

Surgery for snoring	Banerjee and Dempster ⁴¹ [**]/**]

However, it was originally intended to complement other forms of health-related quality of life measures. It has been widely used and its test–retest reliability is good.⁵⁰

SPECIFIC INSTRUMENTS

Disease- or condition-specific

The aim of these instruments is to provide the patient's perception of the problems related to a specific disease or condition. It should be remembered that disease may have a broad impact on the patient's life. To make these instruments comprehensive, a detailed survey of patients suffering from the condition should be conducted when developing the instrument. They may also not detect problems associated with a disease and its treatment that have not been anticipated by the developers if patients have not been involved in the planning. As all of the questions are developed specifically to assess a particular health problem, the content should be very relevant for use in studies of that condition: high validity. They are more likely to detect changes that occur in that particular condition as there should be few if any irrelevant questions: high responsiveness. They are also more acceptable to patients as the relevance of the questions to their condition is obvious so completion rates should be high.

The major disadvantage of disease-specific instruments is that they do not allow comparison to be made with other patient groups with other diseases or conditions. Such comparisons require generic instruments designed for use with any health problem, and for this reason it is often useful to combine a specific instrument with a generic one.

VERTIGO

The Dizziness Handicap Inventory (DHI) is a 25-item questionnaire designed to measure the self-perceived disability and handicap caused by dizziness or imbalance.⁵¹ [**] They reported good internal consistency and test–retest repeatability. The questions were grouped in three domains of functional, emotional and physical aspects of dizziness with three possible answers to each question: yes, sometimes and no. The questions were selected from an initial bank of 37 questions chosen from the case histories of patients. They take a clinical perspective of disability and handicap in daily activities and therefore content validity should be carefully inspected before choosing this instrument for use in a trial. It is preferable to have more input from patients in the selection of items to include in a questionnaire (see Face and content validity above). This instrument has been widely used in studies of imbalance in general.

The Vertigo Handicap Questionnaire (VHQ) was developed from patients' accounts of the problems that

they experienced with vertigo.⁵² [**] It has 25 questions about restriction of physical and social activities and emotional distress, each scored on a five-point Likert scale. It has good reliability and validity but has not been widely used.

HEARING

There are many instruments that have been developed for use in audiology. Assessing hearing disability has one major difference from assessing most other disabilities in otolaryngology – there is a gold standard – pure-tone audiometry. One of the most widely used measures is the Hearing Handicap Inventory for the Elderly (HHIE).⁵³ [**] This instrument has been shown to have good face and content validity.⁵⁴ [***]

While there are reliable tools for measuring hearing, assessment of the efficacy of hearing aid provision and comparison of benefits from different prescription strategies are heavily reliant on patient-based outcome measures. The HHIE has been used for this purpose,⁵⁵ but it has been shown to have poor precision when changes in the HHIE were compared with changes in the Speech Intelligibility Index when using a hearing aid.⁵⁶ [**] This is probably because the HHIE predominantly assesses the emotional and psychological response to hearing impairment. The Glasgow Hearing Aid Benefit Profile (GHABP) was developed as a measure of hearing disability and the benefit obtained from the use of a hearing aid.⁵⁷ It assesses unaided disability, handicap, benefit from a hearing aid, residual disability and patient satisfaction in eight listening situations – four specified and four chosen by the patient. It has good validity in assessing the outcome of hearing aid fitting, high test–retest repeatability and good patient acceptability. It is now used as one of the primary outcome measures in the National Health Service (NHS) programme of modernizing hearing aid services in England. Details of the questionnaire and its use can be found at www.ihr.gla.ac.uk.

OTITIS MEDIA

The OM6 was developed for use in children with recurrent acute otitis media and otitis media with effusion.⁵⁸ [**] Six domains (physical suffering, hearing loss, speech impairment, emotional distress, activity limitation, caregiver concerns) are each addressed by a single question. Test–retest repeatability was high, and responsiveness was demonstrated by a significant change in scores after surgery for ventilation tube insertion.⁵⁹ [**] The criterion validity has been questioned, however, in that it does not correlate well with other markers of disease severity, such as audiometry and severity of symptoms of recurrent acute otitis media.⁶⁰ Kubba *et al.*⁶⁰ suggested that the instrument lacks precision as it does not differentiate between children with otitis media and others with sore throats.

CANCER

The European Organization for Research and Treatment of Cancer Quality of Life Study Group developed the EORTC QLQ-C30 as an instrument of 30 items for use in international trials in cancer.⁶¹ [***] Further modules have been developed which can be added to the core instrument to provide assessment of specific cancers, for example head and neck cancer.⁶² [**] This allows collection of data for comparison across cancer groups and additional data that are particularly relevant to specific cancers.

Site-specific

These instruments contain items that are particularly relevant to patients having treatment for a specific region of the body and should be sensitive to changes experienced by patients following treatment in that region. They are particularly useful in otolaryngology and have the advantage that patient groups are not limited to a specific disease classification. They thus allow comparison of patients with similar symptoms but different pathology. Because they have a narrow focus, they are unlikely to detect any change in broader aspects of health or quality of life following intervention.

SINONASAL DISEASE

Many patient-based outcome measures have been designed for use in sinonasal disease. The 20-item Sino-Nasal Outcome Test (SNOT-20)⁶³ is a modification of the previously used 31-item Rhinosinusitis Outcome Measure (RSOM-31).²² [**] The 20 questions refer to specific sinonasal symptoms and some general health questions. It has good internal consistency (Cronbach's alpha 0.9), and showed good responsiveness to change. Face and content validity seemed good and the construct validity was high when compared with clinical assessment of disease. Test-retest scores were highly correlated ($r=0.9$) though this measures the association between tests rather than repeatability (see Reproducibility above). Piccirillo *et al.*⁶³ report the SNOT-20 to be a valid outcome measure in their particular research setting. The questionnaire is easily completed by the patient and acceptability is high. [**]

VOICE

There is no generally accepted objective test to serve as a 'gold standard' for the assessment of voice disorders. Various questionnaires have been developed for evaluation of the consequences of dysphonia. The Voice Handicap Index (VHI) was designed to assess the self-perceived effect on quality of life of voice disorders.⁶⁴ It is a 30-item questionnaire divided into three subscales: functional handicap, emotional handicap and physical

handicap. The questions use a five-point Likert scale. It has been used to assess the impact of a number of voice disorders, including vocal cord polyps, cord palsy, spasmodic dysphonia and functional disorders. Its construct validity has been confirmed by comparing its subscales with appropriate subscales of the SF-36 in assessment of the health-related quality of life in patients after treatment for laryngeal cancer.²⁵ [**] Significant improvements in VHI scores occurred after treatment of spasmodic dysphonia with botulinum toxin.⁶⁵ [**]

Dimension-specific

These instruments assess one specific aspect of health status. The most commonly assessed dimension is psychological well-being. Another common dimension, more relevant to otolaryngology, is pain. The McGill Pain Questionnaire is one of the most widely used measures of pain severity for both clinical and research purposes.⁶⁶ It comprises 20 subclasses of pain descriptors that provide pain severity scores across sensory-discriminative, motivational-affective and cognitive-evaluative dimensions. It has been found to have good short-term repeatability in chronic pain conditions, and it discriminates well between different types of pain syndromes. A short form of the McGill Pain Questionnaire has been developed.⁶⁷ [***/**] It is highly correlated with the original longer version and has comparable sensitivity. It may be a useful instrument in situations in which the standard questionnaire takes too long to administer.

The advantage of dimension-specific instruments is that they provide a more detailed assessment in the area of concern than is possible in more general instruments. They are perhaps most useful in a study where they are used in combination with another instrument.²⁰ [***]

HOW TO CHOOSE PATIENT-BASED OUTCOME MEASURE

The choice of patient-based outcome measure depends on the purpose of the study. To assess the effects on health-related quality of life of a disease or condition, a generic instrument is required. Specific instruments are of little value as they do not allow comparison with other conditions. A specific instrument may provide additional information by assessing the severity of the disease if no objective measure is available, for example in tinnitus. Comparison of the scores from the specific instrument with the generic instrument may be valuable.

If the aim of the study is to assess the efficacy of treatment, it is usually recommended that two instruments be combined, a generic and a specific instrument. The two different measures are likely to produce complementary evidence. A disease-specific measure will be more responsive to the main effects of intervention,

and therefore produce the evidence most relevant to the clinician. A generic measure may allow comparisons across interventions and disease groups, but is likely to be relatively insensitive to the effects of the intervention. It is possible, however, that the additional burden on the patient may reduce overall compliance, especially if there is overlap between questions in the two instruments.

WHICH GENERIC INSTRUMENT?

Acceptability to the patient and feasibility of completing the questionnaires are obviously important. The time required to complete the commonly used instruments varies. The HUI Mark II takes three minutes, the SF-36 ten minutes and the SIP 20 minutes.⁶⁸ [**]

Appropriateness depends on the study. Utility measures are, in general, only appropriate for studies with large numbers of subjects. Small studies would probably be better to choose a generic health status questionnaire. Some generic instruments have been shown to be better than others in assessing patient with particular problems. Edelman *et al.*⁶⁸ reported that the HUI was better used for evaluating relatively healthy populations because of some floor effects, while the SIP was better for more severely ill populations as their study patients were grouped at the healthy end of the scale. Other authors have similarly reported that the SIP has ceiling effects.^{69, 70, 71} [***/**]

A careful evaluation of reports of the use of these instruments in similar patient groups and study settings should be carried out before making a final choice. In the absence of this, the SF-36 appears to be the safest choice. The HUI Mark III is suitable for large studies and has the advantage for otolaryngology research of including items about hearing and speech.

Deficiencies in current knowledge and areas for future research

Development of a valid and acceptable patient-based outcome measure takes a great deal of time and effort. Large numbers of subjects are needed as development requires several stages. Patient involvement in the selection of items is essential. There have been many patient-based outcome measures that have been reported once and never used again. On the other hand, the currently available and widely used patient-based outcome measures are not ideal. We need better ones.

KEY POINTS

- Patient-based outcome measures assess the patient's subjective experience of illness and of treatment.
- Generic instruments access a broad range of aspects of health status and enable comparisons across different groups of patients with diverse conditions.
- Specific instruments are more sensitive to the effects of specific diseases or conditions, but do not allow comparison to be made with other patient groups with other diseases or conditions.
- It is often useful to combine a specific instrument with a generic instrument.

Introduction	645	Conclusion	648
Definition of EBM	645	Key points	648
The application of EBM	647	References	648

INTRODUCTION

Doctors want to give their patients the best treatment they can, i.e. the treatment that is most likely to help the individual patient in front of them. The idea behind evidence-based medicine (EBM) is that healthcare practitioners should only use (prescribe, recommend, implement) therapies that have been proven to be effective, and should not use unproven therapies that may be ineffective at best or, at worst, actually harmful. By 'harmful' we do not necessarily mean 'fatal' or even imply that the harm is serious. Any outcome which disadvantages the patient – their health, lifestyle, even their wallet or purse – might be considered as a harm, or, if not strictly a harm, a factor to be balanced against any benefit which is accrued as a result of the treatment.

The reader may ask – 'so what's new?' Surely the approach described has been at the heart of medical treatment for centuries. It has been suggested that rather than thinking of the pre-EBM era as being unscientific, we should refer to the present as a time in which we make 'better use of evidence in medicine'. The paternalistic and authoritarian approach that characterized much of medical practice in the past should be replaced by one which acknowledges uncertainty more explicitly, and which operates within a defined framework and with a set of rules for the weighing of scientific evidence.

In 1995, Davidoff *et al.*¹ listed five linked ideas in which EBM is rooted.

1. Clinical decisions should be based on the best available scientific evidence;
2. The clinical problem – rather than habits or protocols – should determine the type of evidence to be sought;

3. Identifying the best evidence means using epidemiological and biostatistical ways of thinking;
4. Conclusions derived from identifying and critically appraising evidence are useful only if put into action in managing patients or making healthcare decisions;
5. Performance should be constantly evaluated.

DEFINITION OF EBM

The most familiar definition of EBM was coined by Sackett and his colleagues in 1996: 'Evidence-based medicine is the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients'.² This concise statement contains many, but not all, the important features of EBM. Before unpacking this description on EBM, it is worth recalling that 'EBM... can be seen as a tool, and tools can be used for good and for ill'.³ It is important that the user knows how to use the tool correctly and does not use it unwisely or inappropriately.

Conscientious

The conscientious otolaryngologist wants to 'do the right thing' for his patient – to do more good than harm. He should also want to do this in the right way. In other words, to 'do things right' – do them better, more efficiently, etc. Muir Gray refers to this practice as 'doing the right things right'.⁴ The term 'conscientious' also brings to mind a certain carefulness and attention to

detail. These characteristics are clearly a requisite for high quality surgery and many practitioners hone and practice their surgical skills in order to improve them. The same diligence with which they do this, the same desire to master their craft, should be directed to acquiring the skills of critical appraisal and data synthesis necessary to practise EBM successfully.

Explicit

Openness and transparency are features of the modern health service in the UK. They are also key elements of rigorous science – prerequisites for allowing experimental work to be evaluated and replicated. One of the principles underlying evidence-based practice is that the methods used are clearly stated and, whenever possible, are stated *a priori*. This explicitness allows others to evaluate and criticize the methods used and, when appropriate, to make the necessary changes to allow the quality of the work to be improved.

Evidence-based practice explicitly evaluates the strength of the evidence underlying a particular intervention or recommendation. By critically appraising a study, specific questions can be answered about the validity of the evidence it contains. How good is it? Can we really believe the results? How certain (or, more usually, uncertain) are we about the results?

This notion of explicitness extends to consideration of issues of uncertainty. In the past, otolaryngologists, like many other physicians, may have found being open and explicit about the uncertainty which surrounds much medical practice, difficult. They have found sharing this with their patients even more so. As new concepts of doctor–patient partnerships (in distinction to doctor–patient relationships) have developed, this approach has become untenable. In the modern health service ‘doctors have the difficult task of explaining the nature of uncertainty and risk in the practice of today’s scientific medicine’.⁵

Judicious

The use of the term ‘judicious’ reminds us that clinical practice must be rooted in considered opinions and sensible decisions. In other words, the evidence has been evaluated and ‘weighed’, benefits being considered and balanced against harms. Common sense has not been ignored. It is a truism to say ‘evidence is necessary but not sufficient’. It needs to be integrated with patient’s preferences (of which more below), economic constraints, organizational factors relating to the delivering healthcare organization and ethical obligations. All this is also to be considered in the context of social responsibility and resource allocation prioritization.

Current best evidence

It may once have been possible for the conscientious otolaryngologist to keep their knowledge comprehensive and up-to-date by reading a few journals every month and going to occasional conferences. In the twenty-first century it is impossible. There are now in excess of two million articles per year published in the biomedical press. The internet has resulted in an explosion of knowledge sources which must be acknowledged, even if the quality of their contents is at times uncertain. Whereas once this knowledge was available only to the select few, now it is available to everyone – doctor, patient, carer and healthcare provider.

Whilst this ‘sea change in the availability of knowledge offers a tremendous opportunity for the health professions to engage the public in taking an interest in and responsibility for their own health ... for some medical practitioners, and indeed for some members of other health professions, this democracy in information access can pose troubling questions. How does one negotiate differences in the interpretation of medical evidence between doctor and patients? How does one signal which evidence is reliable and which is not? How does one offer advice in the face of lack of evidence?’⁵

The practitioner of EBM needs to be able to locate the evidence relating to the clinical question or questions posed by the patient in front of him, and then assess its quality to determine if it is the ‘best’ – and most appropriate – available. In Chapter 52, Critical appraisal skills, Martin Dawes discusses the concept of levels of evidence; suffice it to say at this stage that practitioners need to be aware that just because something is written in a distinguished journal, it does not mean that this represents absolute scientific truth. In the same way that EBM challenges ‘**eminence** based medicine’ (the concept that age, authority and seniority *per se* bring with them an inevitable certainty of valid clinical truth), it also challenges a presumption that published studies are always well designed, well conducted and well reported.

Concepts of publishing have changed in recent years, but paper-based journals and textbooks continue to be produced, and the best ones can form a starting point for the clinician’s enquiries. However, it is likely that greater use will be made of electronic resources and in particular electronic databases such as MEDLINE and EMBASE.

Assistance in identifying and searching appropriate databases is often available from hospital librarians and information specialists. There are a number of electronic resources which house material that has already been assembled, appraised and included because of its methodological quality and can provide a ‘short cut’ to ‘best evidence’. These include the Cochrane Central Register of Controlled Trials (CENTRAL), part of *The Cochrane Library*, the ENT and Audiology Library of the National Library for Health and Clinical Evidence, published by the BMJ publishing group (**Table 51.1**).

Making decisions about the care of individual patients

The original definition of EBM focuses on individual patients, yet EBM is often criticized because the evidence that its practitioners use is derived from groups or populations. The opponents of EBM constantly emphasize their interest in the individual in front of them. The questions they should be asking are these: is my patient so different from those patients who have been evaluated in well-conducted scientific studies that the valid results demonstrating that the treatment is likely to be effective do not apply to them? Or, when studies do show a treatment to be effective, can I be certain that my patient is so different that I would reasonably expect them to respond positively, and without any harms of that treatment outweighing the benefits?

Sackett's definition might be criticized for the use of the phrase 'making decisions'. This suggests that the doctor is making the decision on behalf of the patient. It might be considered more appropriate for the patient to make the decision with the help and assistance of the doctor. Equally, the definition says nothing of the integration of the management options with the patient's values and beliefs. These must always play an important part in the decision-making process. The following modified definition of EBM is proposed:

Evidence-based medicine is the conscientious, explicit and judicious use of current best evidence in helping individual patients to make healthcare decisions that respect their personal values and beliefs.

THE APPLICATION OF EBM

Since its original description and definition, the role of EBM has been extended from the individual patient to

groups and populations of patients. It has become an integral part of modern healthcare practice. However, it is not without its critics and a number of particular issues merit consideration.

EBM has its limitations and these must be recognized. Unfortunately, over-zealous and enthusiastic promotion and practice, which ignores the underlying methodologies or loses focus on individual patients, can lead it into disrepute. It has been said that EBM provides 'a natural environment' for the randomized controlled trial (RCT). The attentive reader will note that this is the first mention of RCTs. Whilst it is true that these help provide the highest 'level' of evidence, they are certainly not a *sine qua non* for the practice of EBM. Indeed, it has been argued that the focus on RCTs may provide a 'selective imbalance' in the nature of the evidence available. For example, it is far more likely that there will be RCT evidence available about pharmacological interventions, compared with complex behavioural interventions, physical therapy, surgery, etc. This reflects the fact that a large amount of 'effort' (including commercial funding and support) is likely to have been put into generating this evidence and the outcomes are often more easily quantifiable.⁶ As a result, pharmacological treatments for a condition may appear to be 'evidence-based' because high quality evidence does exist, whereas nonpharmacological treatments (which may in fact be as, or more, effective) are seen as being nonevidence based, simply because they have not been evaluated by RCTs. The greater availability of evidence for certain types of intervention reflects biases in the research agenda. This is produced by several factors but includes the lack of a mechanism whereby the agenda can be set by the health needs of communities.

EBM has been criticized for focusing too much on 'mainstream' medicine. It is undoubtedly true that there is more, and generally better quality, evidence available about traditional medical interventions. However, one advantage of the arrival of EBM has been that those who promote 'complementary' medicine understand the nature of the rules by which the effectiveness of these therapies will be judged. As a result, there are increasing numbers of systematic reviews and RCTs of interventions in the field of complementary medicine.

In addition to embracing the involvement of complementary practitioners, EBM-oriented organizations, such as the Cochrane Collaboration, have tried to widen and encourage participation by consumers. This involvement, in parallel with the explicit involvement of patients in making their own healthcare choices, has helped engage and empower patients in a way that should increase both their confidence in, and compliance with,⁵ treatment. Conversely, this has been seen as a threat to the professional autonomy of doctors and a challenge to their therapeutic freedom. Unsurprisingly, the challenge to the 'paternalistic and authoritarian nature of much medical practice' has been resisted in some quarters. Interestingly,

a recent Royal College of Physicians Working Party which examined issues of medical professionalism,⁵ suggested the abandonment of the word autonomy from the definition of a professional, not least because the word can be open to misinterpretation. Too often the word suggests 'an appeal to personal authority – that is, the right to pursue a practice that is entirely self-generated'. Whereas 'the doctor should tailor his or her care to the expressed needs of the patient in the light of reliable scientific evidence'.

CONCLUSION

The EBM era is characterized by the better use of evidence in medical practice. Finding that evidence, appraising it and integrating it into the advice given to individual patients is a key part of modern medical practice. Otolaryngologists should apply themselves to the study of EBM methodologies with the same perseverance and diligence as they give to the acquisition of their surgical skills.

KEY POINTS

- Evidence-based medicine is a key component of modern medical practice.
- Evidence is necessary but not sufficient.
- All otolaryngologists should acquire the fundamental skills of searching, appraising and synthesizing required to practice EBM and should do so with the same diligence they apply to learning surgical skills.

WHY DO WE NEED CRITICAL APPRAISAL?

Evidence-based practice (EBP) begins and ends with patients. We can harm patients by giving inaccurate information about prognosis, make assumptions about diagnostic test results that are false, give therapy that is ineffective or harmful, or fail to give effective therapy. The only way to prevent this happening is to ensure that we have the most up to date knowledge available so that we can share that information with patients.

There were 27 randomized control trials published last year just about otitis media. There is no possibility that by reading a couple of journals per week and attending postgraduate seminars that doctors will be able to keep up to date with everything that is important that may affect their patients. EBP starts with the clinician accepting that there is uncertainty about what we do and that sometimes (when that uncertainty occurs frequently or when it is important) we should search for the latest knowledge. Pragmatically, what we do at present is ask colleagues. The flaw with this is the inability to assess the quality of the evidence that is presented to you by your colleague. Does this matter? If the question is important or frequent then yes, it does matter.

Research evidence can be approached from two angles. The first is the clinician who wants to undertake research and the second is the clinician who wants an answer to a clinical question. The latter wants to know what to believe. Is it the randomized trial, or the case series or case-control trial? What papers should they look for to answer their question?

Levels of evidence have been proposed to help clinicians identify trials most likely to yield the 'truth'

and associated with these are grades of recommendation (see the tables in the Appendix to this chapter). For questions about the efficacy of a therapy, these state that a systematic review of homogenous trials is likely to be the most believable evidence.

The process of EBP therefore requires that one searches for the best evidence. For therapeutic decisions, this is usually going to be a systematic review where the authors have searched for and combined, where appropriate, the data from the randomized control trials on that topic. It has the advantage of doing the hard work for you as well as this combination of data in the form of a meta-analysis. Systematic reviews are important as they include the data from all the trials up to that date. It is this that is important and is the hard work. A normal search for papers to be included in the review will often produce a list of more than a thousand papers, and all the titles and abstracts must be read to select relevant articles. The full text of these relevant articles must then be obtained (in itself a time-consuming and expensive task) and read to ensure they meet the selection criteria. The data then have to be independently abstracted from the selected articles. Undertaking a valid, well carried out systematic review is no easy task, but is essential for clinicians to determine the latest evidence.

Once a trial or trials have been found that seems to answer your question, one has to check three things. Is the study valid? What are the results? Can these be applied to my patients?

The need to check for validity seems, on the surface, to be bizarre. Surely this is what journals should be doing. That assumption is correct but in reality the job of a journal is primarily to make a profit. Therefore one will

find articles with flawed trials in even the most highly cited journals.¹

Journals started as the diaries of researchers. These were then passed around colleagues so that the information could be shared. The development of trials and the assessment of bias are subsequent to that descriptive era. What we are now faced with are seemingly complex long papers with obscure statistical analyses. The scenario is no different to a medical student facing their first anatomy class. By reading around the subject and by practice, one is able to quickly identify key anatomical structures. The same is true of reading scientific articles. One can learn certain aspects of trial design very quickly to be able to assess whether an appropriate design was used for a certain research question. The journal *Evidence Based Medicine* critically appraises the literature from over 100 journals. However, it only includes a few that are likely to change the way you think about a problem or change the way you practise. Sadly for the other articles, we must appraise them ourselves.

The need to assess the methodology of individual trials is extremely important. In large systematic reviews of the same clinical outcome with the same therapy, researchers have compared the results of those trials that were randomized and those that were not randomized. There are some large differences in certain studies that are more than one would expect by chance. One cannot always say that randomized trials show less effect than nonrandomized trials.²

However, it is not enough to accept that a trial is believable at face value. There is now overwhelming evidence that trial methodology has a major influence on the results of therapeutic trials.^{2,3} Concealment of randomization, masking and randomization itself are three main components of randomized trial design. The numbers of patients involved in the study and their follow up are the other key features.

If there is not concealment of randomization, this may exaggerate the efficacy of the treatment by as much as 30 percent more than trials where there is adequate concealment. Surprisingly, perhaps of lesser importance is blinding (masking) – the doctor looking after the patient, or the patient themselves, knowing whether they are giving (being given) the experimental or placebo treatment. If there is no blinding, the results may exaggerate the effectiveness of the treatment by 15 percent. If less than 80 percent of patients are followed up, one cannot tell what is happening and the results become meaningless.

To assess a study there are checklists (see the **Figures** in the Appendix to this chapter), some of which have now been incorporated into computer programmes such as that found at the Centre for Evidence-Based Medicine website (www.cebm.net) that enable health professionals to appraise the quality of the evidence for themselves.

Systematic reviews therefore need to assess the individual validity of the trials that are included. If they do not assess whether there was concealed randomization,

for example, then you, the reader, may be given incorrect information. Assessing the quality of a randomized controlled trial may be carried out using a Jadad score or other systems.⁴ Despite the Quorum statement⁵ setting out how systematic reviews should be presented, their quality may be poor.⁶

For systematic reviews, effective transparent searches and defined inclusion and exclusion criteria are important. The homogeneity (similarity) of the studies is also critical in determining whether a meta-analysis of the data is appropriate. The meta-analysis (combination of the results of the individual trials) is usually only appropriate when there is clinical and methodological homogeneity (that is, the methods and clinical outcomes and starting points are similar). In addition, the results must be put into context of present formats of care.

The need to understand how trials may come to the ‘wrong’ conclusion is as important as understating the treatment itself. Clearly, all this may be daunting to a busy clinician so there are sensible short cuts. Always start by looking at evidence that has already been appraised such as that in *Evidence Based Medicine* and *Clinical Evidence*. The essential part of effective clinical practice is to continue to ask questions.

We need to make sure that what we do is based on the soundest evidence possible. If the only evidence is experiential and anecdotal then that is perfectly satisfactory. However, if there is a systematic review of randomized control trials that all point to an alternative treatment being more effective then that should only be ignored at your patients’ peril.

TIPS FOR PRACTISING EVIDENCE-BASED HEALTH CARE

Tip 1: Ask questions

Try making one question per patient. Select one question because:

- There is likely to be an answer.
- The question has arisen more than once or is important;
 - use a sticky label or write down the patient’s name;
 - record briefly the problem for example ‘chronic obstructive pulmonary disease’;
 - write down the question, for example ‘are steroids an effective treatment (mortality and morbidity)?’;
 - put them in your pocket and look at them at the end of the week.

Tip 2: Searching

- Search one ‘question regularly: every two weeks, every month or every quarter!

- Conduct your search in a logical order:
 - clinical evidence;
 - journal EBM;
 - Cochrane;
 - Medline.

Often you will find too few articles, or that the articles you do find are not in your library or will take a long time to obtain. Sometimes you will find too many articles and a systematic review is needed. Unless you have time and the question is desperately important, pass and move on to the next question – let someone else answer this one!

Appraise only the article(s) that answers your question, have the highest level of evidence and are readily available.

Tip 3: Appraisal

- Look for letters about the article in subsequent issues of the journal.
- Appraise with others until confident.
- Appraise using worksheets or using software, for example CATmaker.
- Mark (highlight) on the printed article where you found the important data.
- Get someone else to check it for you.

Tip 4: Share your knowledge

- Try sharing uncertainty with your colleagues.
- Discuss your questions with colleagues (maybe they have already answered them).
- Find fault with the article(s) rather than your colleagues.

BASICS OF CRITICAL APPRAISAL

Read the abstract

Assuming you have three or four articles to appraise, how should you start? First read the abstract. Read it briefly trying to gain an overview firstly of the methods used and secondly the results. For example, a parent brings in a child referred by their GP for recurrent epistaxis but is worried about surgery (describing cautery in dramatic terms) and wonders whether a cream used by a friend's child might help (Naseptin). You make a note of this and later formulate the question 'In children with recurrent epistaxis, is Naseptin effective, compared with placebo, at reducing attacks of epistaxis?' and find this paper.⁷ The abstract is available on line. It takes a minute or two to read through the abstract:

Epistaxis is common in children. Trials show antiseptic cream is as effective as cautery, but it is not known whether either is better than no treatment. We wished

to know the efficacy of cream in children with recurrent epistaxis. The design was a single-blind, prospective, randomized controlled trial set in the otolaryngology clinic in a children's hospital.

The participants were 103 children referred by their general practitioner for recurrent epistaxis. Excluded were those with suspected tumours, bleeding disorders or allergies to constituents of the cream. Referral letters were randomized to treatment and no treatment groups.

Treatment was antiseptic cream to the nose twice daily for four weeks, which was prescribed by the general practitioner before clinic attendance. All children were given an appointment for eight weeks after randomization.

The main outcome measures were the proportion of children in each group with no epistaxis in the four weeks preceding clinic review. Complete data were available for 88 (85 percent) of the children. Of the treatment group, 26/47 (55 percent) had no epistaxis in the four weeks before the clinic appointment. Of the controls, 12/41 (29 percent) had no epistaxis over the four weeks. This is a relative risk reduction of 47 percent for persistent bleeding (95 percent CI 9–69 percent) and an absolute risk reduction of 26 percent (95 percent CI 12–40 percent), giving a number needed to treat of 3.8 (95 percent CI 2.5–8.5).

We conclude that antiseptic cream is an effective treatment for recurrent epistaxis in children.

The format of any abstract should be similar to this. If there is a complex description of the trial that is confusing, ask yourself why? Is it because the authors are hiding an overall negative result or is it really a necessary peculiar design?

So, in this study there were 103 patients with epistaxis in a single blind randomized controlled trial with various outcomes described and a promising result overall.

Does the paper answer the question you are asking?

This is a qualitative judgement that you must make on reading the abstract. If it is the highest level of evidence (systematic review) and it deals specifically with your question then you are home and dry (apart from having to critically appraise the review!). Often though this is not the case, in which case you must look for individual randomized controlled trials that address the specific outcomes relevant to your patient.

Find answers to the validity questions using a checklist for the relevant study

It is very much easier to read an article when you know what you are looking for. The same occurs when an experienced doctor finds it easier to filter the enormous

number of questions and signs they can ask or examine for, and homes in on specific areas they think are relevant. This ability to put the patient's symptoms quickly into context is the key to skilful practice. In exactly the same way, learning what to look for in a research article is key. When teaching medical students, we give exactly the same list of questions that are shown below. This gives them focus and they will work through an article in ten minutes answering all the validity questions.

The first place to check for validity questions about the methods employed is, not surprisingly, in the methods section of the paper. However, you will frequently find certain elements of the methodology may be mentioned in the introduction, results or even the discussion. So if you cannot find out, for example, the rate of follow up in the methods, then scan the rest of the text for the answer.

What sort of research design is the trial?

You may have to resort to checking the methods section of the paper to obtain this. This was a randomized control trial with single blinding.

Assess the level of bias

At this stage one has all the methodology neatly summarized. For example, in this paper there were some problems with follow up. They had data available on 88 of the 103 patients randomized, but 15 of these were assessed by telephone. This introduces an element of bias that may reduce the validity. If this was less than 80 percent then really the trial is so severely compromised that one cannot make any interpretation of the result. If there is not concealed randomization (see under Concealed randomization) then the results *may* overestimate the effectiveness by 30 percent. So, assessing bias is the art of appraisal. In the end you have to decide whether the effect of the treatment demonstrated is likely, taking into consideration the level of bias, to translate into benefit in your patient.

Translate the results into something clinically meaningful

If the article talks about risk reduction, how does that translate into my patient? A frequent term used now is numbers needed to treat. This puts the effect into the context of the patient and lets them decide whether the benefit is worth the trouble or potential side effect.

How can I implement this?

Does this help my practice either by reinforcing what I know and making me more confident or does it change

my practice. If it is the latter, how am I going to go about implementing that change?

The numbers

The most frequent fear expressed is that of the statistics. How can I tell whether these were the correct statistics to be used? I tackle this obliquely. First, ask yourself what is likely to be a beneficial outcome for your patients. Is a reduction in mortality of 1 percent enough for this invasive procedure, or should it be 5 percent? This is by far the most important feature of the results. If the trial was designed to establish a benefit that you regard as clinically insignificant then you can stop reading!

Let us assume you settle for a 5 percent reduction in mortality, for example. The results of the trial say that this was achieved. The statistical test is there to show you that this difference was very unlikely to have occurred by chance in two ways. First, that the difference observed in this trial was unlikely to have happened by chance (p value) and, second, if this trial were repeated 100 times, 95 percent of the trials would have shown a similar result (confidence interval). How they determine the p value (i.e. with a Student t test or a chi-square is beyond the scope of this article but a quick tip is to check the letters written in response to the article because if the article is in a major journal, statisticians will be quick to point out the incorrect use of statistics). In our experience, there is much less use of incorrect statistical tests than there is of poor trial methodology.

To summarize, check that the difference is clinically significant and did not occur by chance.

Summary

Critical appraisal is a logical way of assessing the likely truth of a piece of research, evaluating the results in terms of individual patient care, and then assessing the whole and determining whether it is useful for your practice. It combines some knowledge of trial design, a small amount of basic arithmetic and some qualitative judgements.

FORMING ANSWERABLE QUESTIONS

The reason we do not usually ask questions is they are so difficult to answer. This was clearly illustrated in the *Hitchhiker's Guide to the Galaxy* when the super computer gave the answer '42' to the Ultimate Question of Life, the Universe, and Everything.⁸ The people asking the question were horrified and angry. The computer calmly suggested that, instead of panicking, they should go back and consider the question and that he would of course help them do this. Clearly, this is an extreme example of where the question has been so badly formed that the answer is meaningless.

I see a patient with diabetes. Their control had been haphazard and they had had repeated HbA1c's performed over the last year. Their control seems better now but the HbA1c test is expensive to perform. I wonder how effective is blood glucose at monitoring diabetes. I do a search for 'blood glucose' and 'diabetes mellitus' and turn up 25,000 articles.

I went wrong in two places. You may have spotted that my search was unstructured; the search terms were so vague that I was unable to generate a manageable list of relevant items. However, this arose partly because of the unfocused nature of my question. I want to know how 'effective' the test is. What do I mean by that? If it is negative does that rule out poor control – or if it is positive (high) does that mean they have poor control. In my case it is the former that really is of interest.

We could have gone to a textbook and read thoroughly about diabetes, but we do not have the time, and textbooks are often many years out of date. There are many questions that arise from any consultation and being human we can only deal with those that are most important. In this case it may have been 'diabetic control'. However if I was a medical student and wanted just to know more about diabetes, then a textbook is an excellent place to start. For understanding more about therapy in general, a resource such as *Clinical Evidence*⁹ is extremely valuable (*Clinical Evidence* cites all the evidence from which therapeutic recommendations are made). This form of enquiry is termed a 'background question' or one that helps the person understand the problem in general. This in contrast to what is being discussed here, which are termed 'foreground questions' or decision-making questions. As a student, one asks mainly background questions but as one's experience with a condition increases and the clinical need for decision-making increases, the proportion of background questions fall as the foreground questions rise (Figure 52.1).

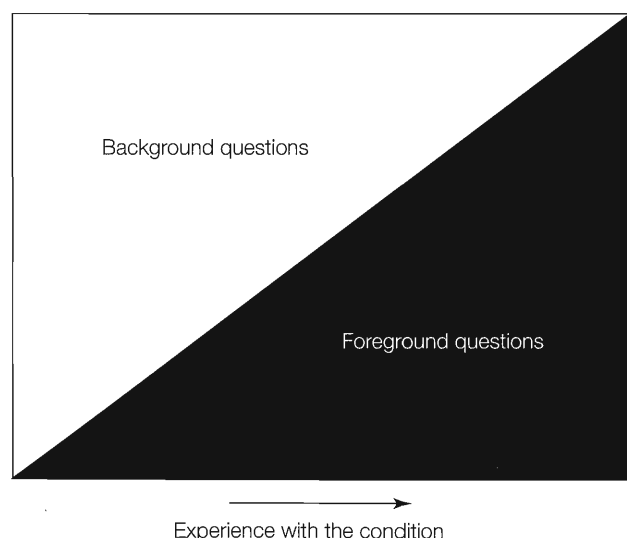

Figure 52.1 Foreground and background questions.

My question now is: 'In diabetics, is fasting blood glucose (compared with HbA1c) effective at excluding poor diabetic control?'¹⁰ (a fasting blood glucose <7.8 rules out poor glycaemic control).

The query is becoming better but the first part is still vague. Perhaps I should enter something about non-insulin dependent diabetics. By structuring a question the answer may be found more efficiently.¹¹ It is therefore important to try to break the question down into several parts:

- patient and problem;
- intervention (or diagnostic test);
- comparison intervention (optional);
- outcomes (PICO).

Patient and problem

The first part is to identify the problem or the patient. Some health care problems are not always about patients! For example, an administrator may want to know whether having acute medical beds in a temporary holding ward next to the accident and emergency department is any better than having conventional acute medical wards in the hospital. Make sure at this stage in the question you are describing the problem or patients that you see. However, if one is too specific at this stage you may miss some important evidence and there is a balance to be struck between obtaining evidence about exactly your group of patients and obtaining all the evidence about all groups of patients.

Intervention

The intervention is equally important. It may in fact be a postponement of an action, such as an operation. In patients with abdominal pain lasting less than 12 hours, does an additional 24-hour delay before referral to hospital alter outcome? Most interventions are more straightforward, such as types of dressings, drug therapies or counselling. Alternatively, they can be about the provision of differing environmental factors, such as the décor of waiting rooms or dealing with the way in which information is given to patients, i.e. positively or negatively.¹²

The intervention can be a diagnostic test. However, specify whether you are trying to detect or exclude a disease.

Comparison intervention

Sometimes, there is a comparison of the intervention. For example, one might seek papers comparing the use of an active compound compared with either a placebo or

another active drug. Considering whether you are looking for comparative studies will help when searching for that evidence. You may be comparing one diagnostic test against another.

Outcomes

Outcome measures are particularly important when considering the question. It is worth spending some time working out exactly what it is you want. In serious diseases it is often easy to concentrate on the mortality and miss the important aspects of morbidity. For example, the use of toxic chemotherapies for cancer may affect both aspects. This is also the time when it is important to know what outcome is relevant to the patient. In Menière's, deafness and tinnitus may occur but the patient may only really be interested in controlling one problem as a priority. The search should primarily focus on that outcome.

Type of question

Once we have created a question, it is helpful to think about what type of question you are asking, as this will affect where you look for the answer and what type of research you can expect to provide the answer. For example, although randomized controlled trials (RCTs) are a very valid type of study, it would be unethical to perform an RCT on harm (would you volunteer for the exposure arm of such a study?). Questions about harm should look for different types of research, such as case-control studies or cohort studies.

APPRAISING DIAGNOSIS ARTICLES

Diagnoses are usually made through interpreting and combining information from a combination of the clinical history, examination findings and the results of investigations, such as blood tests and x-rays. An important component of evidence-based health care is working out how useful these different pieces of information are in making a diagnosis. For example, if you test a patient's urine and find protein in it, how likely is it that this represents kidney disease? A test result needs to be interpreted in the light of how accurate you think the test is, and what you already know about the patient.

In making a diagnosis you are consciously (or subconsciously) weighing up probabilities. Each question you ask or each observation changes those probabilities. For example, if a patient limps in then there is a probability of arthritis being the cause of the limp. If the patient is 70 years of age, the probability is higher than if the patient is 30. The age of the patient is a diagnostic test, either increasing or decreasing the probability. It is

essential that when contemplating a test that the person requesting the test has some idea of the probability of the diagnosis. They will also need to decide whether the test is helping them exclude or include the diagnosis. Finally, they need to know what is the likely probability of the diagnosis after a positive or a negative result.

What is meant by test accuracy? Accuracy is a description of how well the test diagnoses and excludes the disease when the result is positive or negative (see under What are the results?).

Sensitivity reflects the ability of a test to identify people who have disease and specificity reflects the ability of the test to identify 'normality', or people who do not have disease. So this means that tests with very high sensitivities and specificities can be extremely useful at either excluding or including a diagnosis. In primary care some of our time is spent seeing the worried well. These are patients who present with symptoms caused by a mild or self-limiting disease but are naturally worried that it may be something more serious. In these cases we want to use tests that mainly exclude disease. In hospital we are seeing people who are ill and we quickly want to make a diagnosis (including disease).

To see an example of how high sensitivity and specificity values of a test can be used in clinical practice, let us consider how general practitioners deal with patients with a sore throat. We see many sore throats in general practice and it would be useful to know whether a new 'rapid test' could be useful in helping diagnose bacterial sore throats.¹³ I selected this particular paper for illustrative purposes rather than it being the 'best' level of evidence.

This paper was about better diagnosis of throat infections in general practice. Four features of patients were determined:

1. fever $\geq 38^{\circ}\text{C}$;
2. lack of cough;
3. tonsillar exudates;
4. anterior cervical lymphadenopathy.

Five hundred and fifty-eight patients older than 11 years presenting with sore throat were swabbed and examined for these features. They all also had a rapid streptococcal antigen detection test for detecting group-A B-haemolytic streptococcus (GABHS).

The next step was to go through the paper checking for validity.

Is the study valid?

- *Did the authors answer the question?* The question is often found at the end of the introduction section of the paper. Some authors leave you guessing as to what the original question might have been. If the paper does not have a clear question, it cannot give any clear answer, so you can save yourself time by

moving on to the next paper. You should also consider whether the research question is relevant to your clinical question.

- *What were the characteristics of the groups?* This would contain some description about the numbers of patients, their race and gender, age and any other features that are pertinent to the study.
- *Is it clear how the test was carried out?* To be able to apply the results of the study to your own clinical practice, you need to be confident that the test is performed in the same way in your setting, as it was in the study. What was the test undertaken? How was it done and by whom? Was it a multi-level test (i.e. a serum level) with different thresholds?
- *Is the test result reproducible?* This is essentially asking whether you obtain the same result if different people carry out the test, or if the test is carried out at different times on the same person.
- *Was the reference standard (gold standard) appropriate?* To start with, we need to find out how the study found out what the 'truth' really was about patients. That is to say, how did the investigators know whether or not someone really had a disease? To do this, they will have needed some reference standard test (or series of tests) which they know 'always' tells the truth.
- *Were the reference standard and the diagnostic test interpreted blind and independently of each other?* If the study investigators know the result of the reference standard test, this might influence their interpretation of the diagnostic test and *vice versa*.
- *Was the reference standard applied to all patients?* Ideally, both the test being evaluated and the reference standard should be carried out on all patients in the study. There may be a temptation, for example, if the test under investigation proves positive, not to bother administering the reference standard test. In many cases, the reference standard test may be invasive and may expose the patient to some risk and/or discomfort. While it would usually be ethical to use such a test on a patient in whom one had grounds to suspect that it might be positive, it would not be ethical if one thought that the test would be negative (i.e. if the diagnostic test being evaluated had been negative). Therefore, when reading the paper, you need to find out whether the reference standard was applied to all patients, and if it was not look at what steps the investigators took to find out what the 'truth' was in patients who did not have the reference test.
- *Was the test evaluated on an appropriate spectrum of patients?* Another complication is that a test may perform differently depending upon the sort of patients on whom it is carried out. For example, the more severe is a disease, the easier it tends to be to detect. Thus, you might find that testing for bacterial sore throats might be 'better' at detecting infection

when evaluated in patients who attend an ENT clinic, than in those attending family practice. These may be because people with chronic disease who attend an ENT clinic will be more symptomatic and have more bacteria in general, making it easier to detect. This problem is referred to as spectrum bias. A test is going to perform better in terms of detecting people with disease if it is used to identify it in people in whom the disease is more severe, or advanced. Similarly, the test will produce more false-positive results if it is carried out on patients with other diseases that might mimic the disease that is being tested for.

The issue to consider when appraising a paper is whether the test was evaluated on the typical sort of patients in whom the test would be carried out in real life.

The optimal study method for the assessment of a diagnostic test is a cohort study evaluating the test in a group of patients thought to be at risk of having the disease. A less valid alternative method that has been used is a case-control study. The latter method studies patients known to have the disease and control patients without the disease. The performance of the test in the two groups is compared. This sort of study has been shown to overestimate the effectiveness of the diagnostic tests.¹⁴

What are the results?

In an ideal world, a positive test would mean that someone has disease, and a negative test would mean they do not have disease. Unfortunately, this is rarely the case. When a test is carried out, there are four possible outcomes:

1. The test can correctly detect disease that is present (a true positive result).
2. The test can detect disease when it is really absent (a false-positive result).
3. The test can correctly identify that someone does not have the disease (a true negative result).
4. The test can identify someone as being free of a disease when it is really present (a false-negative result).

These possible outcomes are illustrated in **Table 52.1**.

Given that a test may potentially mislead us if we obtain a false-positive or a false-negative result, we need to have some way of characterizing how accurate the test really is (**Table 52.2**). What does this mean? The high specificity means that there were very few people (16) out of the 375 people who did not have GABHS. So that means (using some reverse logic) that if the rapid test was positive (going across the row), by inference they almost certainly have the disease.

We can simplify this to say that in tests with high **specificities**, where the result is **positive**, it rules the diagnosis **in**. The mnemonic for this is **SpPIN**.

Table 52.1 Possible outcomes of a diagnostic test.

Test result	'Truth'		
	Disease present	Disease absent	Totals
Positive	a True positive	b False positive	a + b
Negative	c False negative	d True negative	c + d
Totals	a + c	b + d	a + b + c + d

Sensitivity = $a/(a + c)$ Positive predictive value = $a/(a + b)$.
Specificity = $d/(b + d)$ Negative predictive value = $d/(c + d)$.
Prevalence = $(a + c)/(a + b + c + d)$.
Accuracy = $a + d/a + b + c + d$.

Table 52.2 Results of rapid test screening for group-A B-haemolytic streptococcus (GABHS) in patients with sore throat.

	'Truth'		
	GABHS +ve	GABHS – ve	Totals
Positive	119	16	135
Negative	64	359	423
Totals	211	375	558

Sensitivity = $119/211 = 65\%$.
Specificity = $359/375 = 96\%$.
Positive predictive value = $119/135 = 88\%$.
Negative predictive value = $359/423 = 85\%$.
Prevalence = $211/558 = 33\%$.
Accuracy = $478/558 = 85\%$.

In tests with high **sensitivities** and the test is **negative** then it rules **out** the disease. So the mnemonic for this is **SnNO**ut. Clearly it is not 100 percent accurate at excluding (that would only happen if the sensitivity was 100 percent). How you take that finding and put it into practice depends on the severity of the disease as well as the other symptoms and signs that indicate the pretest probability of the disease.

In reality, patients who are well where you are trying to exclude disease need tests with high sensitivities (primary care). Patients who are ill need tests with high specificities to determine the cause of the illness. This is an oversimplification of the process of diagnosis but is helpful in terms of remembering what tests do.

Often, of course, we are faced with tests whose sensitivity and specificity are not so high that we can use the test to rule in or rule out a disorder. For such cases, we need a measure of a particular test result's ability to predict the presence or absence of disease.

We might think that this is provided by the positive and negative predictive values (for positive and negative results, respectively). However, in practice we find that these values can change depending on the prevalence of the target disorder amongst the test population: if the

Table 52.3 Potential results of rapid test screening for GABHS in patients with sore throat in an imaginary low prevalence setting.

	'Truth'		
	GABHS +ve	GABHS – ve	Totals
Positive	12	16	28
Negative	6	359	365
Totals	18	375	393

Sensitivity = 67%.
Specificity = 96%.
Positive predictive value = 43%.
Negative predictive value = 98%.
Prevalence = 4.5%.

disorder is more common, the positive predictive value will be higher and the negative predictive value lower.

For example, if the results are as follows with a much lower prevalence (**Table 52.3**). The sensitivity remains similar and the specificity is the same but the positive predictive value drops considerably. Now the test only has a 50:50 chance of detecting someone with disease. You can see how the prevalence will sometimes significantly alter the effectiveness of a test. It is important to always consider the setting before recommending tests that perform well in an alternative health care setting.

However, since sensitivity and specificity are not affected by disease prevalence, we can combine them to create a combined measure of the efficacy of a particular test result. This can be thought of as, for a given test result, the likelihood that a patient with the disorder would yield that test results compared to the likelihood that a patient without the disorder would yield that same test result. This is the likelihood ratio (LR). As a rule of thumb, for positive test results, an LR of ten or above shows that the test result is good at ruling in disease; for negative test results, an LR of 0.1 or less shows that the test result is good at ruling out disease.

Two additional benefits of the LR are that they can be used to generate specific post-test probabilities for your patient and that, where we have multiple independent tests, the LRs can be multiplied together to yield a much more powerful test.

The prevalence of GABHS was 33 percent. If the test is positive it is very likely they have GABHS, but what about if it is negative?

What I can do though is work out the likelihood ratios:

Likelihood ratio (+ve result)

$$= \frac{\text{Sensitivity}}{(100\% - \text{specificity})} = \frac{0.65}{(1 - 0.96)} = 16.25$$

Likelihood ratio (–ve result)

$$= \frac{(100\% - \text{sensitivity})}{\text{specificity}} = \frac{(1 - 0.65)}{0.96} = 0.36$$

Figure 52.2 shows the nomogram for likelihood ratios. To use the nomogram I have drawn a line from the pretest probability of 33 percent through 16 (on the likelihood ratio line) to obtain a post-test probability of approximately 90 percent if the result is positive and through 0.36 (roughly) to obtain a post-test probability of approximately 12 percent if the result is negative.

But what if our patient has a lower pretest probability? For example, this might be a patient with only a 20 percent pretest probability. Using a ruler, see what their post-test probability would be. The nomogram lets you quickly see the implications of a positive or negative result in terms of post-test probability.

Will the results help my patient?

ARE THE RESULTS RELEVANT TO YOUR PATIENT?

So far, we have considered how to interpret results of tests for your patients. However, it may be that you feel that the results of studies carried out to assess the accuracy of the test are not generalizable (or relevant) to your setting, or you may consider that it would not be helpful to your patient to perform the test.

GENERALIZABILITY TO YOUR SETTING

One aspect to consider is whether the assessment(s) that have been carried out of test validity are applicable to your setting. We have already seen how predictive value is dependent upon prevalence, so the predictive value of a test in one setting is usually not the same in another setting. Sensitivity and specificity (and likelihood ratios) are not dependent on prevalence, but they can vary according to the type of patients on which the test is carried out. The sensitivity of a test will depend upon the severity of disease in the population being tested. The more advanced or severe the disease, the more likely the test is to identify it.

The specificity of a test will depend upon the prevalence of other diseases in the population that might lead to false-positive results. The more that other diseases are present, the more likely a false-positive result.

A second aspect to consider is whether the test is carried out the same way in your setting as it was in the study. Some diagnostic tests depend upon the skill of the person carrying out the test, and the skill of the people interpreting the test result. Tests may be carried out in different ways, and it is important to know that it is carried out the same way in your local hospital or laboratory as it was in the study which evaluated the test.

WILL IT HELP YOUR PATIENT?

One way to think about whether or not to perform the test is whether it will influence the management of the

Figure 52.2 Nomogram for likelihood ratios.

patient or groups of patients you are likely to see. If you think that a disease is unlikely in a particular patient, it may be that if you carried out the test and it was positive, you would still think that the disease was unlikely, so it would not influence your management. Conversely, if you think that a disease is likely in a given patient, it may be that a negative test result would not stop you treating the patient, since you would still think that the disease is likely whatever the test result. Putting this in terms of pre- and post-test probabilities, in the first instance the pretest probability of disease is so low, that even with a positive test result, the post-test probability will be less than 50 percent. In the second instance, the pretest probability of disease is so high that even with a negative test result, the post-test probability will be more than 50 percent.

In practice, knowledge about the accuracy of diagnostic tests will perhaps be most useful when planning protocols or guidelines to manage particular groups of patients.

Summary

An evidence-based approach to deciding whether a test is effective for your patient involves the following steps:

- frame the clinical question;
- search for evidence concerning the accuracy of the test;
- assess the methods used to determine the accuracy of the test;
- find out the likelihood ratios for the test;
- estimate the pretest probability of disease in your patient;
- apply the likelihood ratios to this pretest probability using the nomogram to determine what the post-test probability would be for different possible test results;
- decide whether or not to perform the test on the basis of your assessment of whether it will influence the care of the patient, and the patient's attitude to different possible outcomes.

APPRAISING THERAPY ARTICLES

When we are required to answer a question about therapy, the identification of information from an article is not straightforward. The layout is frequently different depending on the journal you are reading. One is often relying on the editorial board of the journal, as well as the people who reviewed the article, to have ensured the quality of the article. There may be confusing statistics that make interpretation of the data seem difficult. These problems seem to be very daunting when one is trying to identify information that may affect the care of a patient. These following questions will help you identify the real validity of the therapy article.

- *Is the study valid?* Did the authors answer the question? For this example I shall be using the Kubba paper⁷ on Naseptin and epistaxis. The abstract of this article is shown under Read the abstract. Kubba *et al.*⁷ have answered their question about the effectiveness of Naseptin in epistaxis. They state clearly how they did this and what they used to determine 'effective'.
- *What were the characteristics of the groups?* This would contain some description about the numbers of patients, their race and gender, age and any other features that are pertinent to the study. This is usually found in Table 1 in most papers but in this case is described in the protocol part of the subjects and methods section.
- *Are the comparison groups similar?* To determine whether bias has occurred in the selection procedure, certain potentially relevant characteristics of the two populations should be displayed in tabular form. Usually these include age, sex, duration of illness and other demographic and functional characteristics. This is covered in the first paragraph of the results section of this paper. There were more boys than girls, but the age and duration of history were the same in both groups. Is it likely that girls and boys would differ in response? The aim is not to find if there are statistical differences between the two groups but to find whether there are clinically significant differences. You as a clinician reader should judge whether you think the differences are clinically significant.
- *What was the treatment?* In this case it was either Naseptin or nothing. They describe clearly the reasons for not using a placebo.

Equal treatment

The groups in the trial were treated equally throughout apart from the experimental intervention. It should be clear from the article that, for example, there were no co-interventions that were applied to one group but not the other, or more frequent or detailed assessments on one group compared to the other.

Placebo control

Patients do better if they think they are receiving a treatment than if they do not, even if the treatment is an inactive substance: the placebo effect is a widely accepted potential bias in trials. A placebo is an inactive treatment that is given so that the patient does not know whether he or she has been given the active treatment; the control group in a trial will often receive a placebo treatment so that this effect is equal in both groups. Patients in both

groups of the trial should not know whether or not they are receiving the active therapy. However there is a twist in the tail – one can have a placebo-controlled trial where the patients are having active treatments in both arms of the study in addition to the new treatment or the placebo. So the term ‘placebo-controlled trial’ does not exclude the use of active treatments (as long as both groups get the same).

Follow up

There are three major aspects to assessing the follow up of trials:

1. Did so many patients drop out of the trial that its results are in doubt?
2. Was the study long enough to allow outcomes to become manifest?
3. Were patients analysed in the groups to which they were originally assigned (intention-to-treat)?

Drop-out rates

A good clinical trial requires the complete follow up of patients in both the control and experimental groups. If less than 80 percent of patients are adequately followed up then the results may be invalid. In this study they had problems and had to phone subjects as they did not attend the outpatient clinic. They talk about this weakness of the study in the discussion. Does it invalidate the study?

Length of study

The length of the study is critical in determining the clinical significance of the results. For a disease of short duration, such as an acute infectious disease, the period of the study need only be long enough to cover the course of that infection. Where the disease is more progressive and lengthy then the duration of the study needs to reflect that. The question that the research is trying to answer will also be helpful in deciding the appropriate length of the study.

Intention-to-treat

Because anything that happens after randomization can affect the chances that a patient in a trial has an event, it is important that all patients are analysed in the groups to which they were randomized. This is an essential prerequisite for valid evidence about therapy. For example, it has been repeatedly shown that patients who do and do not take their study medicine have very

different outcomes, even when the study medicine they have been prescribed is a placebo. The correct form of analysis, in which patients are analysed in the groups to which they were assigned, is called ‘intention-to-treat’ analysis.

Were the groups randomized?

The major reason for randomization is to prevent bias. The largest potential cause of bias in research about effectiveness of an intervention, is if the patients allocated to the treatment group are different from those allocated to the control group in a way that might influence outcome. To reduce this bias as much as possible, the decision as to which treatment a patient receives should be determined by random allocation. Why is this important?

There could be any number of confounding variables that affect a given situation, some of which we know about, but also others that our knowledge of human physiology has not yet uncovered. Randomization is important because it spreads all confounding variables evenly amongst the study groups, even the ones we do not know about.

CONCEALED RANDOMIZATION

As a supplementary point, clinicians who are recruiting patients into a trial may consciously or unconsciously distort the balance between groups if they know the treatments that will be given to patients. For this reason, it is preferable that the randomization list be concealed from the clinicians. The amount of impact the lack of concealment may have is larger than if the trial was not blinded. If there is inadequate concealment, the size of the effect may be overemphasized by as much as 30 percent.

BLINDING

It is also important that, if possible, both clinician and patient be ‘blind’ to whether or not they are receiving treatment. Lack of blinding may lead to exaggeration of the effectiveness of the therapy by as much as 20 percent.³

Outcome measures

To determine the impact of an intervention on patient health, one needs to define clearly the outcome that needs to be measured. This sounds straightforward enough but can take up a larger amount of the preparation time of the research. An outcome measure is any feature that is recorded to determine the progression of the disease or problem being studied. In this paper a comprehensive questionnaire was used to determine outcomes.

What are the results?

- How large is the treatment effect?
- How precise is the estimate of the treatment effect?

In any clinical therapeutic study there are three explanations for the observed effect:

1. the effect of the treatment.
2. chance variation between the two groups.
3. bias.

Good research will explicitly endeavour to reduce the effects of chance and bias by using special designs, as we have seen.

NUMBERS NEEDED TO TREAT

The most common approach is to describe the effect of a drug in terms of the risk reduction. The risk is usually of continuing to have, for example, pain or an event. When evaluating a paper on a therapeutic manoeuvre, it is possible to establish its clinical effectiveness by determining the proportion of patients receiving treatment who gain benefit.

From the paper the following results are drawn:

This simple statement obscures the fact that identifying the correct table in the paper and then obtaining the correct figures from it is often not as easy as it sounds. This is one of the parts of appraisal that it is often useful to share with others to ensure you have the correct data.

From **Table 52.4** it can be seen that 47 patients were assigned to the active treatment (or experimental) group and 41 to the watchful waiting (or control) group. There were a total of 50 children with epistaxis; 21 occurred in the experimental group and 29 in the control group.

EVENT RATES

It is important to set some standard methods of describing this data. In therapy, we start by converting the numbers of patients into event rates. In the control group, 29 out of 41 patients had epistaxis. This may be presented as an event rate of $(29/41) = 0.71$. So the control

event rate (CER) is 0.71 (this number is also the risk of epistaxis in the control group, and corresponds to a percentage risk of 71 percent).

In the experimental treatment group there were 21 children with epistaxis out of 47 children. The experimental event rate (EER) was therefore 0.44 (44 percent). Now that we have these numbers we can start working with them.

RELATIVE RISK

One way of combining the event rates is to use relative risk (RR). Here, we make a ratio of the two risks to show which group has a higher or lower risk. The relative risk is calculated by dividing the risk of having epistaxis in the treatment group by the risk of the control group $= 0.44/0.71 = 0.62$. This means that the risk of epistaxis continuing with Naseptin was 0.62 (or 62 percent) of the risk without Naseptin.

Relative risk reduction

It is also possible to show the extent of the benefit compared to the original risk by calculating the relative risk reduction (RRR). This is similar to relative risk, except that we take the difference in risk between the two groups and divide that by the control group's risk:

$$RRR = \frac{CER - EER}{CER} = \frac{0.71 - 0.44}{0.71} = 0.38$$

RRRs are often presented as percentages.

The RRR means that the treatment reduced the risk of continued nosebleeds by 38 percent relative to that occurring in this control population (the RRR given by the authors is for persistent bleeding whereas I have calculated for cessation of bleeding). This is a large risk reduction in a population that are all bleeding. But what if it was an RRR for primary stroke reduction where the events are far fewer? So the RRR has to be judged against the prevalence of the outcome we want to prevent.

Absolute risk reduction

The absolute risk is that 71 percent of individuals in the placebo group had nose bleeds and that 44 percent of the treatment group had nosebleeds. The difference (absolute risk reduction (ARR)) between these gives us another view of the effectiveness of the treatment. The ARR of this therapy is 0.27 ($CER - EER = 0.71 - 0.44$).

ARR = CER – EER

Consider 100 people given this treatment. We would expect 27 less children to have epistaxis if this group were given Naseptin than if they were not. We can convert this into how many people we would need to treat to prevent one child continuing to have epistaxis. This number is the reciprocal of the ARR. In this example $1/0.27 = 3.7$. Therefore, to prevent a child continuing to have epistaxis we need to treat four people. This is the number needed

Table 52.4 Results of a trial of Naseptin against watchful waiting in stopping epistaxis in children.

	Epistaxis	No epistaxis for four weeks	Total
Active treatment (Naseptin)	21	26	47
Watchful waiting	29	12	41
Total	50	38	88

to treat (NNT). It is more useful than relative measures because, as well as measuring the benefit of a therapy, it also represents the baseline risk and the absolute benefit you can expect from the therapy.

NNT = 1/ARR

Sometimes, papers will present their results in the form of NNTs, as in this one which is very helpful, but often they do not, and prefer to present risk ratios (perhaps not surprisingly, since these tend to make beneficial results look more spectacular) or similar measures. You will often be required to calculate NNTs from the data in the study. Fortunately, the arithmetic is fairly straightforward. Some other examples of NNTs are included in Bandolier (<http://www.jr2.ox.ac.uk/bandolier/band50/b50-8.html>).

This is a small study and like the relative risk there is a confidence interval around the NNT (to calculate this¹⁵ it is easier to use software (www.ebm.net). Also, there is the 'believability' issue of a relatively small trial. This is where the clinical judgement comes in – would you use this treatment based on 100 patients?

Will the results help my patient?

- Can the results be applied to my patient?
- Were all clinically relevant outcomes considered?
- Are the benefits worth the harms and costs?

Given that your patient was not in the trial and may not even have been eligible for it (due to age, sex, comorbidity, disease severity or for a host of other sociodemographic, biologic or clinical reasons), how can you extrapolate from the external evidence to your individual patient? (We use the term 'extrapolate' here, although this might more accurately be described as 'particularizing' the results of a trial (which looks at a generic population) to your particular patient.) This requires that you apply some of your knowledge of human biology and clinical experience to answer the question: 'Is my patient so different from those in the trial that its results cannot help me make my treatment decision?'

HOW MUCH BENEFIT CAN YOU EXPECT FOR YOUR PATIENT?

Given that you have decided that your patient is sufficiently similar to those in the study for the effect to be applicable, the next questions is how much? Here is one way of going about this.

f Method

First estimate, as a decimal fraction, your patient's risk compared to the control group from the study. Thus, if your patient is twice as susceptible as those in the trial, $f=0.2$; if half as susceptible, $f=0.5$. As long as the treatment produces a constant RRR across a range of susceptibilities, the NNT for your patient is simply the

trial's reported NNT divided by f . (This is a big assumption and we are only beginning to learn when assuming a constant RRR is appropriate (for numerous medical treatments such as antihypertensive drugs) and inappropriate (for some operations such as carotid endarterectomy, where the RRR rises with increasing susceptibility). So, in the above example, we might assign an f of 0.7 (70 percent chance of having epistaxis to the control group of subjects), which would yield an NNT of $(3.7/0.7) = 5$.

INCORPORATING YOUR PATIENT'S VALUES AND PREFERENCES

What does your patient think? Have you talked to them about their personal preferences, concerns and expectations? Here, we must try to determine whether the outcome of the therapy actually serves the values and preferences of the patient. Many factors can come into play, not least the difficulty of representing them. Sometimes, the situation may be very clear-cut or demand immediate action. For example, in a patient having a heart attack, the value of survival and the preference for a simple, low-risk intervention such as aspirin, given the efficacy of this regimen, usually makes this decision quickly agreed and acted upon. In other cases, the answer may take weeks and several visits to sort out, such as in choosing between radiation and adjuvant chemotherapy for stage II carcinoma of the breast.

These questions are perhaps the most important, yet have the least written about them in this chapter. That is because they are also the most complex and depend to a great extent on the clinical situation.

Summary

An evidence-based approach to deciding whether a therapy is effective for your patient involves the following steps.

1. Frame the clinical question.
2. Search for evidence concerning the accuracy of the test.
3. Assess the methods used to carry out the trial of the therapy.
4. Determine the NNT of the therapy.
5. Decide whether the NNT can apply to your patient, and estimate a particularized NNT.
6. Incorporate your patient's values and preferences in to deciding on a course of action.

APPRAISING SYSTEMATIC REVIEWS

What happens when there is more than one randomized control trial on the same treatment or diagnostic test? In

this case you want to look for a paper that has combined these trials together.

What you need here is a systematic review, a publication that collects all of the evidence in a particular area and summarizes it. More formally, a systematic review is 'a review of a clearly formulated question that uses systematic and explicit methods to identify, select and critically appraise relevant research, and to collect and analyse data from studies that are included in the review. Statistical methods may or may not be used to analyse and summarise the results of the included studies.'

This section will look at how you appraise studies that search for all research on a specific question and in some way combine it.

You may be familiar with the narrative reviews traditionally found in many journals. Normally someone, usually an expert, looks at the evidence in a certain area. Mulrow¹⁶ argues that traditional reviews do not routinely use systematic methods to identify, assess and synthesize information. Thus, normally there is no methods section for the actual conduct of the review. The reader then has no way of knowing whether the review is based on a systematic review of the evidence, or on a collection of papers that the author has found in a less systematic way and thus the evidence presented may not be complete. There is a need for systematic reviews of the evidence. This needs to be undertaken in just as rigorous a way as any primary piece of research, with a clear question and explicit methods for all stages of the process, such that another person could replicate the review. Three key features of such a review are:

1. a strenuous effort to locate all original reports on the topic of interest;
2. critical evaluation of the reports;
3. conclusions are drawn based on a synthesis of studies which meet preset quality criteria.

When synthesizing results, a meta-analysis may be undertaken. This is 'the use of statistical techniques in a systematic review to integrate the results of the included studies', which means that the authors have attempted to synthesize the different results into one overall statistic.

Where can you find systematic reviews?

Systematic reviews have been published in a variety of journals, and in addition the Cochrane Collaboration provides an important resource in this area. The Cochrane Collaboration is an international collaboration that is committed to 'preparing, maintaining and disseminating systematic reviews of the effects of health care'. It promotes and publishes the Cochrane Library (<http://www.cochrane.org>). This contains the Cochrane Database of Systematic Reviews. These reviews have a prespecified protocol, where every stage of the process of undertaking the review is made explicit.

Sections covered in a protocol include background, objectives, criteria for considering studies for the review (including types of participants, types of interventions, types of outcome measure, types of study), search strategy for identification of studies, study selection, methodological quality assessment, data extraction, meta-analysis, the comparisons to be made, subgroup analysis and sensitivity analysis to be undertaken. The point to note here is that all these aspects of the protocol are set out before the review is undertaken.

Many of the systematic reviews so far completed are based on evidence of effectiveness of an intervention from RCTs.

Is the review valid

In this section we will focus on systematic reviews of therapy. Of course, systematic reviews exist for other types of research.¹⁷

- *What databases and other sources did the authors of this review search?* The paper should give a comprehensive account of the sources consulted in the search for relevant papers, and the search strategy used to find them. Since standard databases fail to correctly index up to half of published trials, and negative trials are less likely to be published in the first place, the search strategy should include hand searching of journals and searching for unpublished literature. Other questions to ask yourself about the search strategy are: Have any obvious databases been missed? Did the authors check the reference lists of articles and of textbooks? Did they contact experts (to obtain their list of references checked for completeness and to attempt to find out about ongoing or unpublished research)? Search terms used are also important – has an obvious medical subject heading (MeSH) (a standard thesaurus for medical indexing) term been missed or is there another term they have not used? For example, when searching for papers looking at care of the elderly, use of the term 'senior' in the North American literature may be overlooked. Searching should include languages other than English. Unpublished data are useful to include because studies with significant results are more likely to be published than studies without significant results, known as publication bias. For example, research which is carried out by non-English language teams is more likely to be published in English if it shows a strong result in favour of an intervention than if it shows a negative or indifferent result.
- *How the studies were selected – eligibility criteria?* You should look for a statement of how the trial's validity was assessed, using criteria such as those in the therapy guides. It is particularly reassuring when two or more investigators applied these criteria

independently and achieved good agreement in their results. You need to know what criteria were used to select the research. This should include who the study participants were, what was done and what outcomes were assessed. A point to consider is that the narrower the inclusion criteria, the less generalizable are the results. However, this needs to be balanced with using very broad inclusion criteria, when heterogeneity becomes an issue. Such studies may cover a wide range of patients and/or interventions and/or outcomes and the justification for then combining these differing groups comes into question. The importance of a clear statement of inclusion criteria is that studies should be selected on the basis of these criteria (that is, any study that matches these criteria is included) rather than selecting the study on the basis of the results.

- *How were the data abstracted?* Data are usually obtained by two individuals working separately (independently) and then compared later. Often the data are not available within the paper and there may be a statement about obtaining the raw data from the authors.
- *Is there a description of the quality of each trial?* A table of the studies meeting the inclusion criteria should include some data on the validity checks itemized in the section on randomized control trials.⁴
- *Were the results consistent from study to study?* Although we might expect some variation from study to study, we would be concerned if some trials confidently concluded a beneficial effect of the therapy, while others confidently concluded harmful or no effects. Unless this heterogeneity can be explained to your satisfaction (such as by differences in patients, dosage or duration of treatment), this should lead you to be very cautious about believing any overall conclusion about efficacy from the review.

Statistical heterogeneity exists when there is greater variation between the results than is likely due to chance. The chi-square statistic on which they are based has on average a value equal to its degrees of freedom. Values much larger than the degrees of freedom suggest a smaller *p* value and thus significant statistical heterogeneity. This means greater variation exists between the studies than is likely by chance alone. One might then conclude that the studies are so different that it makes no sense to combine them. Since this test of heterogeneity is described as having a low power, a nonsignificant test cannot be interpreted as evidence of homogeneity. The aim of the authors should be to clearly describe the influences of specific clinical differences between the studies, rather than purely relying on an overall statistical test of heterogeneity.

Clinical and statistical heterogeneity need to be distinguished. Clinical heterogeneity refers to differences between settings, patients, techniques and outcomes,

which might lead you to suggest it does not make sense to combine the data.

What are the results?

Terms that you will probably come across when looking at systematic reviews include odds ratios, relative risks, weighted mean differences and fixed and random effects, amongst others.

BINARY OR CONTINUOUS DATA

The type of data will dictate what you see when you look at a meta-analysis:

- binary data (for example, an event rate: something that happens or it does not, such as myocardial infarction, stroke, improved/not improved) is usually combined using odds ratios;
- continuous data (for example, numbers of days, peak expiratory flow rate) are combined using differences in mean values for treatment and control groups (weighted mean differences (WMD)) when units of measurement are the same (for example, all using the same anxiety scale), or standardized mean differences when units of measurement differ (for example, using a variety of anxiety scales, where one numerical value could mean very different things, depending on the scale used). Here, the difference in means is divided by the pooled standard deviation.

Thus when you look at a meta-analysis, you will see odds ratios or relative risks and/or weighted mean differences or standardized mean differences, depending on the outcomes measures that have been used in the included studies.

ODDS RATIO

Odds are another way of describing risk. The odds of an event are the probability of it occurring compared to the probability of it not occurring. We cannot do a randomized control trial to assess whether gastroesophageal reflux disease (GERD) may be associated with laryngeal neoplasm. However, we can do a case-control study looking at people with and without cancer.¹⁸

We do not know the incidence of laryngeal cancer in the population from this study as they took cases with cancer and compared them to controls, but we can work out the odds (Table 52.5). For GERD, the odds of having cancer is $731/1315 = 0.555$. This clearly is not the risk in the general population! The odds of having laryngeal cancer in non-GERD patients was 0.237. The odds ratio was $0.555/0.237 = 2.3$. So patients with GERD in this study had 2.3 times the odds of having laryngeal carcinoma. This was unadjusted for the other major risk factor of smoking. In large studies, odds ratios approximate risk ratio.

Table 52.5 Prevalence of gastroesophageal reflux disease (GERD) in a case control study of patients with and without laryngeal cancer.

	GERD	No GERD
Laryngeal cancer	731	7497
No laryngeal cancer	1315	31,597
Total	2046	39,094

Clearly, as in randomized controlled trials with risk reduction, unless we know the baseline risk it is impossible to put odds ratios into context. A number needed to treat can be derived from an odds ratio but remember that many assumptions have been made in that process and treat them with some caution.

Many systematic reviews use odds ratios to represent differences between treatment and control groups. Relative risk and absolute risk reduction may also be used to express these sorts of differences, as we have already seen.

WHAT DO ODDS RATIOS USED IN A META-ANALYSIS LOOK LIKE?

The square box or ‘blob’ on the Forrest Plot (which is sometimes known colloquially as a ‘blobogram’) (**Figure 52.3**) is the individual study effect (technically referred to as the point estimate), with its associated confidence interval as lines either side of that box (technically known as the interval estimate). Sometimes the size of the box may

vary to reflect the weight that particular study is given, with larger boxes representing higher weighting. Lower weighted studies are usually those with smaller samples and large confidence intervals. The overall or summary effect (from combining or pooling the studies) is usually depicted as a diamond. Since patients may respond differently to treatment, this pooling may need to be supplanted by summarizing evidence along multiple covariates of interest. Thus, although one overall number is appealing in its simplicity, it may oversimplify a more complex situation.

An odds ratio of one on a linear scale means there is no difference between the experimental and control group. This value of one is the line down the middle of the figure (sometimes with the wording ‘favours treatment’ on one side and ‘favours control’ on the other). If the confidence interval does *not* cross the line, it means that there is a 95 percent chance that there is a true difference between the groups. That is, that there is a significant difference on that particular outcome between the intervention and control groups. If the confidence interval does cross this vertical line labelled ‘1’ it means that any difference in that outcome between the treatments could have occurred by chance (that is, there are no statistically significant differences). It may be that a very wide confidence interval is due to a very small sample size, and it would reduce with more people in the study. A 95 percent confidence interval covers likely results from a set of similar studies. It therefore provides a more realistic view of what will happen in practice than a point estimate, because it takes potential variability into account.

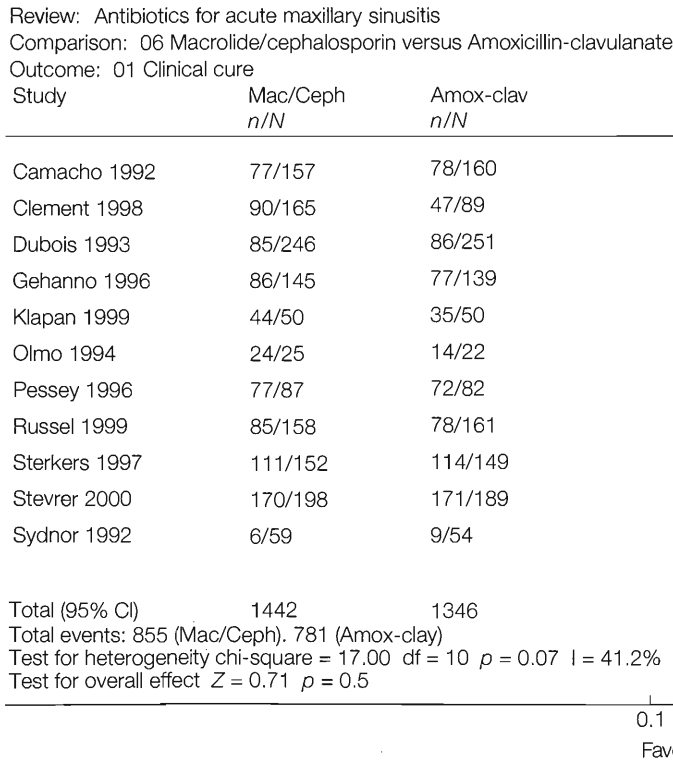

Figure 52.3 A Forrest plot. Redrawn from Ref. 19, with permission.

It is worth noting that a lack of evidence for an intervention is not the same as evidence of a lack of effect.

HOW PRECISE ARE THE RESULTS?

This is asking whether there are any confidence intervals used, so the reader can see the range of values around the effect size, where in one is 95 percent confidence that the 'true' effect would lie. The *Cochrane handbook* (1998), section 6.1, defines precision as 'a measure of the likelihood of random errors. It is reflected in the confidence interval around the estimate of effect from each study ... more precise results are given more weight'. Thus the more precise the results, the narrower (smaller) the confidence interval. NNTs can be calculated from the odds ratios (see Appendix). However, these should be treated with caution as they can oversimplify.

WILL THE RESULTS HELP ME IN CARING FOR MY PATIENTS?

- *Can the results be applied to my patient care?* How similar are the patients you care for to those included in the review? The wider the type of patients included in the review, the more likely you are to feel the results may apply across a range of different patients. However, it is sometimes a difficult decision to know whether, for example, something that works on men will be equally effective on women, or something that works in younger people will work in the same way in older people. Subgroup analysis may be one way of addressing this concern, although there are concerns with this approach.
- *Were all clinically important outcomes considered?* What is clinically important can depend on your perspective. Sometimes, whilst factors such as bone density may be included in a review to assess the effectiveness of certain orthopaedic procedures, it may be some other outcome, such as ability to get to the shops, that needs to be considered as this sort of outcome may be crucial from the patient's perspective.
- *Are the benefits worth the harms and costs?* This may cover a range of factors, such as benefit of early treatment following a positive cervical smear versus the harms of high anxiety. Or it may be the benefits of a chemotherapeutic agent versus its unpleasant side effects. An economic evaluation may be included.

What is sometimes difficult using a set of criteria like this, is that you end up with a variety of no's or can't tell's in answer to the questions you pose. It is sometimes difficult to decide when a review is 'too bad' to give you any confidence in the findings. Perhaps one pragmatic approach would be that when you have several 'no's' or 'can't tell's' you are more wary about the validity and robustness of the review's findings. What this does illustrate is that, like undertaking a systematic review, critically appraising these reviews is not an exact science,

but there are many subjective decisions along the way. Just like undertaking a systematic review, making explicit your decisions in the critical appraisal is therefore very important.

Although a systematic review can provide you with high quality evidence, clinical experience and patient preferences are an important part of evidence-based medicine. It may be that even high quality evidence does not apply to a particular patient. Similarly, Cochrane reviews do not include recommendations, as reviewers cannot know the local situation or the patient, and this is the province of the health professional caring for the patient.

KEY POINTS

Appraising diagnosis articles

- Criteria for validity of diagnosis trials: was there a reference standard, was it appropriate and was it applied blind, independently and to all patients?
- Appropriate spectrum of patients; clear and reproducible description of test, follow up, intention-to-treat.
- Outcome measures.
- Measures of the accuracy of diagnostic tests: sensitivity, specificity, positive predictive value negative predictive value, likelihood ratios.
- Applying the results to your patient: pre- and post-test probability, SpPin and SnNout.

Appraising therapy articles

- Criteria for validity of therapy trials: randomization, blinding, placebo control, equal treatment, follow up, intention-to-treat, outcome measures.
- Measures of the importance of the results of therapy trials: risk, event rates, NNTs.

Appraising systematic reviews

- Criteria for validity of systematic reviews: search for relevant trials, assessment of included trials' quality, heterogeneity.
- Measures of the importance of the results: risk, event rates, NNTs, odd ratios.

APPENDIX

Levels of evidence

Table 52.6 provides a breakdown of the types of research that answers questions on therapy, prognosis, diagnosis, differential diagnosis or prevalence and economic studies.

Table 52.6 Levels of evidence.

Level	Therapy/prevention, aetiology/harm	Prognosis	Diagnosis	Differential diagnosis/symptom prevalence study	Economic and decision analyses
1a	SR (with homogeneity) ^a of RCTs	SR (with homogeneity) ^a of inception cohort studies; CDR ^b validated in different populations	SR (with homogeneity) ^a of Level 1 diagnostic studies; CDR ^b with 1b studies from different clinical centres	SR (with homogeneity) ^a of prospective cohort studies	SR (with homogeneity) ^a of level 1 economic studies
1b	Individual RCT (with narrow Confidence interval) ^c	Individual inception cohort study with >80% follow-up; CDR ^b validated in a single population	Validating ^k cohort study with good ^h reference standards; or CDR ^b tested within one clinical centre	Prospective cohort study with good follow-up ^c	Analysis based on clinically sensible costs or alternatives; systematic review(s) of the evidence; and including multi-way sensitivity analyses
1c	All or none ^d	All or none case-series	Absolute SpPins and SnNouts ^g	All or none case-series	Absolute better-value or worse-value analyses ^j
2a	SR (with homogeneity) ^a of cohort studies	SR (with homogeneity) ^a of either retrospective cohort studies or untreated control groups in RCTs	SR (with homogeneity) ^a of Level >2 diagnostic studies	SR (with homogeneity) ^a of 2b and better studies	SR (with homogeneity) ^a of level >2 economic studies
2b	Individual cohort study (including low quality RCT; e.g., <80% follow-up)	Retrospective cohort study or follow-up of untreated control patients in an RCT; Derivation of CDR ^b or validated on split-sample ^f only	Exploratory ^k cohort study with good ⁱ reference standards; CDR ^b after derivation, or validated only on split-sample ^f or databases	Retrospective cohort study, or poor follow-up	Analysis based on clinically sensible costs or alternatives; limited review(s) of the evidence, or single studies; and including multi-way sensitivity analyses
2c	'Outcomes' research; Ecological studies	'Outcomes' research		Ecological studies	Audit or outcomes research
3a	SR (with homogeneity) ^a of case-control studies		SR (with homogeneity) ^a of 3b and better studies	SR (with homogeneity) ^a of 3b and better studies	SR (with homogeneity) ^a of 3b and better studies
3b	Individual case-control study		Nonconsecutive study; or without consistently applied reference standards	Nonconsecutive cohort study, or very limited population	Analysis based on limited alternatives or costs, poor quality estimates of data, but including sensitivity analyses incorporating clinically sensible variations

4	Case-series (and poor quality cohort and case-control studies) ^c	Case-series (and poor quality prognostic cohort studies) ^l	Case-control study, poor or nonindependent reference standard	Case-series or superseded reference standards	Analysis with no sensitivity analysis
5	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'	Expert opinion without explicit critical appraisal, or based on economic theory or 'first principles'

The levels of evidence used throughout this book are as stated in the prelims on the How to use this book page. These are very similar to the five levels given in this table, except that Levels 3 and 4 of the system described in this table are equivalent to Level 3, and Level 5 (expert opinion) is equivalent to Level 4 in the system used in this book.

Produced by Bob Phillips, Chris Ball, Dave Sackett, Doug Badenoch, Sharon Straus, Brian Haynes and Martin Dawes since November 1998.

Users can add a minus sign '–' to denote the level of that fails to provide a conclusive answer because of:

- EITHER a single result with a wide confidence interval (such that, for example, an ARR in an RCT is not statistically significant but whose confidence intervals fail to exclude clinically important benefit or harm).
- OR a systematic review with troublesome (and statistically significant) heterogeneity.
- Such evidence is inconclusive, and therefore can only generate Grade D recommendations.

^aBy homogeneity we mean a systematic review that is free of worrisome variations (heterogeneity) in the directions and degrees of results between individual studies. Not all systematic reviews with statistically significant heterogeneity need be worrisome, and not all worrisome heterogeneity need be statistically significant. As noted above, studies displaying worrisome heterogeneity should be tagged with a '–' at the end of their designated level.

^bClinical decision rule. (These are algorithms or scoring systems which lead to a prognostic estimation or a diagnostic category.)

^cGood follow-up in a differential diagnosis study is > 80%, with adequate time for alternative diagnoses to emerge (e.g. one to six months acute, one to five years chronic).

^dMet when *all* patients died before the Rx became available, but some now survive on it; or when some patients died before the Rx became available, but *none* now die on it.

^eBy poor quality *cohort* study we mean one that failed to clearly define comparison groups and/or failed to measure exposures and outcomes in the same (preferably blinded), objective way in both exposed and nonexposed individuals and/or failed to identify or appropriately control known confounders and/or failed to carry out a sufficiently long and complete follow-up of patients. By poor quality *case-control* study we mean one that failed to clearly define comparison groups and/or failed to measure exposures and outcomes in the same (preferably blinded), objective way in both cases and controls and/or failed to identify or appropriately control known confounders.

^fSplit-sample validation is achieved by collecting all the information in a single tranche, then artificially dividing this into 'derivation' and 'validation' samples.

^gAn 'Absolute SpPin' is a diagnostic finding whose Specificity is so high that a *Positive* result rules-*in* the diagnosis. An 'Absolute SnNout' is a diagnostic finding whose Sensitivity is so high that a *Negative* result rules-*out* the diagnosis.

^hGood, better, bad and worse refer to the comparisons between treatments in terms of their clinical risks and benefits.

ⁱ*Good* reference standards are independent of the test, and applied blindly or objectively to applied to all patients. *Poor* reference standards are haphazardly applied, but still independent of the test. Use of a nonindependent reference standard (where the 'test' is included in the 'reference', or where the 'testing' affects the 'reference') implies a level 4 study.

^jBetter-value treatments are clearly as good but cheaper, or better at the same or reduced cost. Worse-value treatments are as good and more expensive, or worse and the equally or more expensive.

^kValidating studies test the quality of a specific diagnostic test, based on prior evidence. An exploratory study collects information and trawls the data (e.g. using a regression analysis) to find which factors are 'significant'.

^lBy poor quality prognostic cohort study we mean one in which sampling was biased in favour of patients who already had the target outcome, or the measurement of outcomes was accomplished in < 80% of study patients, or outcomes were determined in an unblinded, nonobjective way, or there was no correction for confounding factors.

Table 52.7 Grades of recommendation.

A	Consistent level 1 studies
B	Consistent level 2 or 3 studies or extrapolations from level 1 studies
C	Level 4 studies or extrapolations from level 2 or 3 studies
D	Level 5 evidence or troublingly inconsistent or inconclusive studies of any level

'Extrapolations' are where data are used in a situation that has potentially clinically important differences than the original study situation.

For each type of research a level of evidence is shown. This helps the reader identify the likely validity of the research. It does not mean that all systematic reviews are 'better' than randomized controlled trials. It should be used more as a pointer for searching and then a guide to the likely level of evidence. If one has a therapeutic question then looking for a systematic review first is logical. If there is no review then one next looks for a randomized controlled trial, etc.

If there is no trial evidence then consensus statements becomes the highest level of evidence answering that question. This just makes the grade of recommendation D rather than A if there was a systematic review. The grades of recommendations vary from country to country and organization to organization and should only be considered as a guide (Table 52.7).

Worksheets

The worksheets shown in Figures 52.4, 52.5 and 52.6 can be used to appraise a randomized controlled trial, a diagnostic study or a systematic review. They are aide memoirs about the items to look for in a paper when appraising the validity, identifying the results and assessing the applicability.

They can be used in journal clubs or in other settings when an important new paper is being discussed. The data from these checklists can be entered into software to make your own electronic database of critical appraisals and saved as web pages or text documents.

Databases searched to find this article	
Citation of article	
Why did you select this article(s)	
Did the authors answer the question?	
1. What databases and other sources did the authors of this review search?	
2. What were their eligibility criteria (inclusion and exclusion) for papers in this study? Do these seem appropriate?	
3. Was their independent data extraction of the results by the reviewers (then compared later)	
4. Is there a description of the quality of each trial included?	
5. Were the results consistent from study to study? (Homogeneous)	

Are the valid results of this systematic review important?

What was the odds ratio?	
What was the control group rate (PEER)	

Can you apply this valid, important evidence from a systematic review in caring for your patient?

Do these results apply to your patient?	
Is your patient so different from those in the overview that its results can not help you? How great would the potential benefit of therapy actually be for your individual patient?	
To calculate the NNT for any OR and PEER $\text{NNT} = \frac{1 - (\text{PEER} * (1 - \text{OR}))}{(1 - \text{PEER}) * \text{PEER} * (1 - \text{OR})}$ Or use calculator from www.cebm.net	

Are your patient's values and preferences satisfied by the regimen and its consequences?

Do your patient and you have a clear assessment of their values and preferences?
Are they met by this regimen and its consequences?
Should you believe apparent qualitative differences in the efficacy of therapy in some subgroups of patients? Only if you can say 'yes' to all of the following:
Do they really make biologic and clinical sense?
Is the qualitative difference both clinically (beneficial for some but useless or harmful for others) and statistically significant?
Was this difference hypothesized before the study began (rather than the product of dredging the data), and has it been confirmed in other, independent studies?
Was this one of just a few subgroup analyses carried out in this study?

INTRODUCTION

Functional magnetic resonance imaging (fMRI) has become one of the most versatile tools in cognitive neuroscience. Using blood oxygenation level-dependent (BOLD) fMRI, grey matter regions active during sensory, motor and cognitive activity can be defined based on the accompanying local increase in blood flow and oxygenation. Increasing numbers of applications to basic questions in auditory physiology have been reported. Now, there is the exciting potential for clinical use of the methodology.

An overview of functional brain imaging methods

Functional brain imaging includes any of a broad range of techniques by which physiological changes accompanying brain activity can be followed. For example, neuronal depolarization can be monitored using

electroencephalography (EEG) or magnetoencephalography (MEG). The energy-requiring metabolic changes in neurons and glia that accompany neurotransmitter release and reuptake and receptor occupancy can be measured using positron emission tomography (PET). Currently, the most commonly used functional brain imaging technique is fMRI. Functional magnetic resonance imaging is sensitive to the increase in local blood flow with neuronal activation. These changes in blood flow can be measured directly using perfusion MRI.¹ However, as the increase in total oxygen delivery exceeds the increase in oxygen utilization, another fMRI method, BOLD fMRI, can also be used. In BOLD fMRI the imaging contrast arises as a consequence of the higher ratio of oxy-to deoxy-haemoglobin in local capillaries and draining venules with brain activity.² While the neuronal events thus are only indirectly observed, the method is widely exploited because of its sensitivity, relatively low cost and ease of examination and the lack of recognized risks.

The different functional brain imaging methods have different temporal and spatial resolutions. Methods that

Figure 53.1 Different forms of contrast can be generated using MRI, identifying structural and functional differences across normal or pathological brains. (a) T1-weighted contrast in the brain of a patient with multiple sclerosis, showing brain tissue as brighter signal and cerebrospinal fluid (CSF) (or areas of tissue matrix destruction) darker. (b) T2-weighted contrast in the brain of a patient with multiple sclerosis. Here CSF is bright as are regions of inflammation with its associated oedema. (c) A contrast-enhanced T1-weighted image from the brain of a patient with multiple sclerosis. A region of acute inflammation with loss of an intact blood-brain barrier allows leak of the gadolinium-DTPA contrast agent into the brain parenchyma, enhancing the signal intensity locally (arrow). (d) BOLD fMRI contrast defines the hand region of the primary sensorimotor cortex during a simple hand movement. The colours represent the statistical significance of signal enhancement during the active vs. the rest phases.

map the transient brain electrical dipoles generated by neuronal depolarization (e.g. EEG) or the associated magnetic dipoles (MEG) define the underlying cortical neuronal events in real time (10–100 msec), but offer relatively poor spatial resolution (on the order of a centimetre or more). PET methods require relatively long acquisition times (tens of seconds) and give moderately high spatial resolution (5–15 mm). Functional magnetic resonance imaging provides information on the increases in blood flow accompanying neuronal activation with potentially rather higher spatial resolution (approximately 1–10 mm), but has a temporal resolution limited by the haemodynamic changes, which are made slower (several seconds) than the neuronal response (milliseconds).

Generation of image contrast in functional magnetic resonance imaging

Let us consider the problem of developing contrast between different tissues in greater detail. How is a difference in signal intensity (image contrast) generated between regions of brain that are ‘active’ and those that are at ‘rest’ in fMRI?

Once the nuclear spins in the tissue are excited by a radiofrequency pulse, they can return (or ‘relax’) to a low energy state by emission of energy. It is this energy, the frequency of which is made to be spatially variable, that is detected in MRI. The rate at which the emissions decay is determined by interactions with the environment. As local (i.e. on a molecular and cellular level) environments for water molecules vary across a heterogeneous tissue such as the brain, this so-called ‘relaxation rate’ also varies. The MRI image can be made sensitive to this by

varying the interpulse delay or ‘TR’ in a pulse sequence. A ‘T1-weighted’ clinical scan generates image contrast using this principle (Figure 53.1). However, while useful for differentiating grey from white matter, this alone does not distinguish ‘active’ from ‘resting’ brain. Some functional information can be introduced by scanning after injection of an MRI contrast agent (e.g. gadolinium DTPA), which can define vessels or regions around vessels that become more permeable to small molecules with inflammation, infarction or tumours by changing the local with relaxation time. However, while the first functional imaging was performed in this way,¹ it remains a cumbersome technique for most applications.

In tissue, huge numbers of spins are being observed simultaneously (in the brain for example, there are more than 4×10^{19} water protons/mm³). Even in a small tissue region, each of the nuclei has a different relation to other molecules and experiences a slightly different, varying local magnetic field. These shifting fields allow an exchange of energy between the nuclei spins. This leads to a faster loss of the net signal from all of the nuclei together. This is described by the so-called ‘spin–spin’ or T2 relaxation time. The T2 is an intrinsic property of nuclei in a particular chemical environment that accounts for the contrast (generated by changing the imaging parameter ‘TE’) in a ‘T2-weighted’ MRI image. While T2 differences are useful for defining differences in, for example, water content between different brain regions (Figure 53.1), they also tell us nothing directly about brain function.

However, a related phenomenon provides the answer. The rate of decay of signal is faster if there are local (i.e. on a molecular scale) magnetic field variations that the molecules can diffuse through over the time course of a single TE. As molecules move through different

magnetic fields, their resonance frequencies change (although only slightly), lowering the coherence of the nuclear spins. This leads to more rapid decay of the net signal. In the presence of local magnetic field inhomogeneities the rate of signal decay is expressed by the $T2^*$ relaxation time. In regions of rapidly changing local magnetic fields (e.g. in tissue adjacent to a blood vessel filled predominantly with paramagnetic deoxyhaemoglobin), the $T2^*$ can be substantially shorter than the $T2$. This mechanism determines the dramatic signal contrast provided by blood breakdown products in tissue for clinical MRI. It is also the mechanism underlying generation of BOLD fMRI images (Figure 53.1).

THE PHYSIOLOGICAL BASIS FOR BLOOD OXYGENATION LEVEL-DEPENDENT FUNCTIONAL MAGNETIC RESONANCE IMAGING

Mechanisms of haemodynamic change

The locally increased blood flow with brain activation is a consequence of increased energy utilization at the synapse.^{3,4} Several processes contribute to this, including increased energy utilization in adjacent astrocytes with the uptake of the excitatory neurotransmitter, glutamate, depolarization of the post-synaptic membrane and subsequent spike discharges.⁵ However, there is not a simple relationship between increased energy utilization and increased blood flow or BOLD fMRI contrast.

'Metabolic' functional imaging techniques, such as BOLD fMRI, can identify activation-related changes in grey matter (where the synapses are found), but not in the white matter. It is important to emphasize that results should be interpreted primarily in terms of synaptic activity, rather than neuronal activity directly.⁶ Because of the lack of a fixed relationship between synaptic energy utilization and neuronal firing, as well as the large number of potentially interacting processes generating the signal, caution should be taken in trying to relate the magnitude of the BOLD response quantitatively to neuronal discharge rate.

Coupling of haemodynamic changes to neuronal activation

Multiple mechanisms contribute to the control of blood flow to the brain and the precise way in which blood flow is coupled to increased metabolic demands with synaptic activity. Nitric oxide (primarily from neuronal nitric oxide synthase) may be the most important chemical signal responsible for local increases in perfusion with neuronal activation and the cerebral vasodilatory response to hypercapnia, but a variety of factors would also

contribute, including K^+ release with neuronal depolarization and H^+ and adenosine release. Locally generated eicosanoids (e.g. prostacyclin)⁷ and circulating factors (e.g. norepinephrine, serotonin) can modulate blood flow regulation, as can some drugs in common use (e.g. theophylline or scopolamine, inhibit the haemodynamic response to neuronal activation).^{8,9} Neuronal-haemodynamic coupling can change with age,¹⁰ although the changes after maturity are modest.¹¹

Perfusion functional magnetic resonance imaging

The most direct approach to measuring functional activation with MRI would be to directly define the changes in perfusion (or the associated small increase in local increase in blood volume) with the accompanying neuronal activation. The first functional MRI studies did just this using a paramagnetic MRI contrast agent to follow changes in local blood volume with increased activation.¹

While technically challenging, a more attractive approach to measuring functional activation changes from direct perfusion measurements is to use noninvasive arterial 'spin-tagging' (Figure 53.2).^{12,13,14} Arterial spin-tagging methods use radiofrequency pulses from the MRI system itself to transiently 'label' flowing blood without the need for an exogenous contrast agent. Unfortunately, the sensitivity of this approach is low, which limits its applicability at present.

© Hodder Arnold / Scott-Brown 7E

Figure 53.2 Both perfusion MRI and BOLD fMRI can be used to define regions active during brain activity. In this study, the subject alternately moved the right hand in flexion-extension or kept it at rest. The hemodynamic response with brain activation in the left primary sensorimotor cortex is shown using: (a) BOLD fMRI; and (b) arterial spin tagging (ASL) perfusion imaging. Similar regions are active, although the perfusion method is less sensitive (giving a smaller activation region). The green target shows the mean and standard deviation (in the plane of the image) of activation centres of gravity with respect to the large sulcal draining vein (blue) identified by MR venography in the same experiment. Images were prepared by Dr. T. Tjandra, FMRI Centre, Oxford.

How is blood oxygenation level-dependent contrast generated?

The most robust and widely used fMRI method is BOLD fMRI. In BOLD fMRI the image signal contrast arises from changes in T_2^* generated with differences in local 'magnetic susceptibility', an index of the extent to which an applied magnetic field is distorted as it interacts with a material, as blood oxygenation changes. Normal blood can be considered simply as a concentrated solution of haemoglobin (10–15 g haemoglobin/100 cm³). When bound to oxygen, haemoglobin is diamagnetic, while deoxygenated haemoglobin is paramagnetic. Magnetic flux is reduced in diamagnetic materials, i.e. the applied magnetic field is repelled. Paramagnetic materials, in contrast, have an increased magnetic flux, i.e. the applied magnetic field is attracted into the material. A change in haemoglobin oxygenation therefore leads to changes in the local distortions of a magnetic field applied to it. 'Gradient echo' MR images of a cat brain show signal loss around blood vessels when the animal is made hypoxic, for example.² More local changes in blood oxygenation, from the increase in the ratio of oxy- to deoxy-haemoglobin specifically in a region of increased blood flow with brain activation, give rise to small local increases in signal intensity.

Diamagnetic: become magnetized in a direction at 180° to the applied magnetic field
Paramagnetic: weakly attracted by magnetic field, does not retain permanent magnetism

PRACTICAL DETAILS

Design of functional magnetic resonance imaging studies

Methods such as PET provide an absolute measure of tissue metabolism. In contrast, BOLD fMRI can be used only for determining relative signal intensity changes associated with different cognitive states during a single imaging session. The most time-efficient approach for comparing brain responses in different states during the imaging experiment is the 'block' design.¹⁵ This design uses relatively long, alternating periods (e.g. 30 s), during each of which a discrete cognitive state is maintained. In the simplest form, there may only be two such states, a 'rest' and an 'active' state (although 'rest' is defined only with respect to the specific activity being considered). These are alternated through the experiment in order to ensure that signal variations from small changes in scanner sensitivity, patient movement or changes in attention have a similar impact on the signal responses associated with each of the different states.

However, it can become difficult to control a cognitive state precisely for the relatively long periods of each block. A 'rest' state is rarely a true rest, as mental events are difficult to constrain in a subject who is not engaged in a specific task. Some types of stimuli (particularly sensory stimuli) may show rapid habituation (a particular

problem in studies of olfaction, for example).¹⁶ Some cognitive tasks simply may not be amenable to a block design. For example, an 'oddball' paradigm (in which the reaction to an unexpected stimulus is probed) cannot be adapted to a classical 'block' design directly.

An alternative approach is so-called single-event fMRI,¹⁷ in which data are acquired while discrete stimuli or responses are given. Results from many trials are then averaged together to give a measurable response. This is a potentially powerful approach, as it allows considerable flexibility for study of responses to individual or periodically presented stimuli, but it demands relative longer acquisition times than the block design.

A related approach is to present stimuli in a periodic fashion and then to map responses in terms of their phase relative to that of the stimulus presentation. This was used first for study of the visual cortex, which is organized functionally in multiple retinotopic maps arranged according to increasing eccentricity and polar angle. Because it is effectively a difference mapping procedure,¹⁸ the edge contrast between adjacent functional regions is emphasized.¹⁹ Tonotopy in the auditory system has been mapped using a similar strategy.²⁰

Analysis of functional magnetic resonance imaging studies

The raw BOLD fMRI data can be acquired over periods as short as a few minutes. If the approach to analysis is well defined, near 'real-time' viewing of final statistical maps of activation is possible (although in research applications exploratory analyses may take substantial periods of time!). The basic problem in analysis of functional imaging experiments is to identify voxels that show signal changes varying with the changing brain states of interest across the serially acquired images. This is a challenging problem for fMRI data because the signal changes are small (leading to potential false-negatives or type II errors) and the number of voxels simultaneously interrogated across the imaged volume is very large (giving potential false-positives or type I errors).

One of the potentially most significant artifacts for fMRI that distinguishes it from other functional imaging techniques is its extreme susceptibility to motion from movements either of the whole head or even the brain alone (e.g. with the respiratory or cardiac cycles).²¹ Effects of small head movements can be reduced by mathematically realigning the brain volumes after the data are first acquired, but larger movements can degrade image quality irrecoverably. This may be a particular confound in studies of patients who may be less comfortable in the magnet environment.

After optimization of the signal-to-noise by digital filtering, analysis of the time course by comparison of the signal of both models of the 'baseline' and 'active' states must be performed. There are many valid ways of

© Hodder Arnold / Scott-Brown 7E

Figure 53.3 New forms of representation of brain activation patterns can make the spatial relationships easier to appreciate. All three images here reflect visual cortex activation associated with watching a flashing checkboard. A 'model-free' analysis using independent components analysis was performed, which distinguishes between the primary visual cortex (orange) and the motion-sensitive, MT cortex (blue). (a) Inflated brain representation; (b) flattened brain representation; (c) spherical brain representation. Images were prepared by Drs S. Smith and C. Beckmann (FMRIB Centre, Oxford, UK) using MELODIC (www.fmrib.ox.ac.uk/fsl) for analysis and the Freesurfer (Athinoula Martinos Imaging Centre, Massachusetts General Hospital NMR Centre, Boston) for representation.

performing statistical comparisons between signals in images acquired during different brain states. A simple approach is to generate a map of the t -statistic for changes on a voxel-by-voxel basis and use this to identify voxels with significance levels exceeding a chosen significance threshold (e.g. $t > 3$, which might correspond in a particular case to $p < 0.01$). A related approach is to correlate the time course of signal change in each voxel with a model time course based on the expected response, which again can be used to generate a t -statistic change.

Valid statistical inference from the image time course data is complicated by the fact that large numbers of voxels are being assessed simultaneously for changes. The significance level must be corrected for the number of truly independent comparisons that are being made. For example, if 10,000 independent voxels are being tested and a threshold for significance of change in each of the individual voxels of $p = 0.05$ is chosen, then 500 ($= 0.05 \times 10,000$) would be 'active' by chance alone! The significance threshold therefore must be made more stringent in proportion to the number of independent comparisons. Fortunately, because observations of immediately neighbouring regions are not really independent, the correction factor is reduced.

There are now a number of software packages produced by academic centres that include a full set of tools for analysis of fMRI data (e.g. FEAT (www.fmri.ox.ac.uk/fsl), SPM (www.fil.ion.ucl.ac.uk/spm/) or AFNI (www.cc.nih.gov/cip/ip_packages/ip_packages.html#afni)).

Neuroanatomical interpretation of functional data for groups of subjects: Use of a common brain space

A strength of fMRI is that it is sensitive enough to allow observations to be made even in individual subjects. Nonetheless, averaging results from studies of many subjects is often useful for identifying areas of activation

common to many members of the group. This can be used to define the 'normal' pattern of behaviour as a basis for detecting pathological patterns in patients, for example. Averaging between brains is possible with the use of a 'common' brain space, a canonical brain shape that can be related easily to the variable anatomy of individuals. The most well-known common brain space was developed by Talairach as a simple geometric parcellation of a single brain according to major anatomical landmarks.²² This has been extended into a probabilistic framework.²³ More abstract representations of spatial variations in activation across the brain are possible using, for example, flattened representations, produced by computationally unfolding the cortex (Figure 53.3).^{24, 25, 26} Other representations using standard geometric shapes for which coordinate systems (which allow relative positions of activations to be described precisely) are derived readily and that demand less distortion (e.g. a sphere) are also possible.²⁷

ILLUSTRATIVE APPLICATIONS OF FUNCTIONAL MAGNETIC RESONANCE IMAGING

Applications of fMRI are growing rapidly and potentially have relevance to several aspects of otolaryngology. Here, applications to selected issues in hearing research are described to illustrate the range of problems that can be studied using the technique.

Imaging the normal auditory system

Functional magnetic resonance imaging has already contributed important information concerning the organization of the human auditory cortex, directly demonstrating parallels with the functional organization of the auditory brain in animals that previously were only assumed.²⁸ For example, tonotopic representations in the

human primary auditory cortex comparable to those identified electrophysiologically in animals have been demonstrated using fMRI.²⁹ Differences between humans and other species have also begun to be defined. Animal studies, for example, have not demonstrated evidence for differences in cortical organization reflecting the sound level of the stimulus, while evidence for this level of representation of 'sound space' has been found in humans.²⁸

One of the most striking areas of difference between humans and animals lies in the relative hemispheric specialization for auditory signal processing. Microelectrode studies in animals have consistently demonstrated a simple contralateral dominance for processing, similar with monaural stimulation to either of the two ears. In contrast, recent fMRI studies have provided evidence for left hemispheric dominance for this process in humans even for pure tones (Devlin *et al.*, unpublished observations) (Figure 53.4a and b). This lateralization for pure tone processing may be central to understanding the specialization of the left hemisphere for language.

In auditory language processing, a left hemisphere dominance has long been recognized. This can be made clear with functional imaging by appropriate choice of contrasts of auditory tasks during the imaging study. Processing associated specifically with language intelligibility is strongly left-lateralized, for example, but this is made apparent only when an unintelligible control ('rest') stimulus of identical auditory complexity is contrasted (Figure 53.4).³⁰

Development of function in the brain may also be studied with these techniques. While the demands for prolonged stationary periods in the unusual environment of the scanner probably preclude direct application of the technique to very young children while awake, responses in primary sensory systems, including audition, can be studied even under conditions of anaesthesia.³¹

© Hodder Arnold / Scott-Brown 7E

Figure 53.4 Functional imaging of audition. A 'sparse-sampling' protocol was used for analysis of auditory and language cortex activation by fMRI. Intelligible vs. unintelligible speech matched for acoustic characteristics were used. Both images show the left hemisphere for a group average activation map. (a) Activation primarily in the region of Heschl's gyrus with acoustic stimulation. (b) Activation primarily in more posterior, language-related regions with presentation of intelligible speech. Images courtesy of Dr. C. Narain and Dr. S. Scott (FMRIB Centre, Oxford).

As described earlier in this chapter, one of the general problems with the use of fMRI to study auditory processing is the noise of the imaging itself. Use of paradigms such as 'sparse sampling' (in which the stimuli are presented during quiet periods, with only intermittent sampling) avoid this problem, but are highly time-inefficient. An intriguing alternative approach that can be used with deaf patients is electrical stimulation via cochlear implants. This strategy poses technical challenges because of magnetic susceptibility image artifacts from the metal and safety concerns regarding the potential for current generation in the wires with gradient switching. However, with proper shielding of the stimulation cables, any induced currents can be reduced to levels below the acoustic perceptual threshold for cochlear implant subjects. In a recent report, stimulation of different intracochlear electrodes was associated with distinct cortical activations, consistent with the known tonotopical organization of the auditory cortex.³²

Defining functional relations between brain regions

An important aspect of fMRI studies is the ability to define potentially interacting regions across broad regions of the brain. This ability to discriminate anatomically specific processing regions sets it apart from electrophysiological methods such as evoked potential studies. Functional magnetic resonance imaging has recently been used to probe the ways in which the brain processes identity and spatial information in sound.³³ In one study, participants had to match two sounds either for pitch or spatial location. Relative to location, pitch processing generated greater activation in the auditory cortex and the inferior frontal gyrus. Conversely, the task of recognizing location generated greater activation in posterior temporal cortex, parietal cortex and the superior frontal sulcus. The specialized auditory processing streams in the human brain implied by these differences are analogous to the 'what' and 'where' segregation of visual information processing, suggesting common modes of information organization.

Another general area of interest catalyzed by functional brain imaging has been understanding the functions of the cerebellum, classically thought of simply as a motor centre. Data now show that the cerebellum is involved in a broad range of tasks (perceptual, as well as motor) that demand representations of temporal information. Temporal sequencing plays an important role in auditory perception. Consistent with this hypothesis, bilateral injury to the cerebellar hemispheres can compromise the ability to make distinctions between words whose differences are determined by the closure time, a purely temporal measure of the lengths of pauses within words. To test for cerebellar involvement with this function, subjects were studied by fMRI to contrast patterns of

brain activation during word discriminations made possible by variations in relative timing or the sound of central consonants.³⁴ The timing categorization selectively activated the right cerebellar cortex (Crus I) and the prefrontal lobe (anterior to Broca's area), while the sound categorization preferentially activated the supratemporal plane of the dominant hemisphere. This suggests that representation of the temporal structure of speech sound sequences is the crucial aspect of cerebellar involvement in cognitive tasks involving auditory comprehension.

Imaging plasticity

Short-term plasticity or 'learning' has become a particularly fruitful area of fMRI-based research. One example of this is in responses to an 'oddball' tone.³⁵ Brain responses elicited to pure tones of 950 Hz (standard) with occasional deviant tones of 952, 954 and 958 Hz were measured before and one week after subjects had been trained in these frequency discriminations. Frequency discrimination improved after the training session for some subjects (T+), but not for others (T-). Haemodynamic responses in the auditory cortex comprising the planum temporale, planum polare and sulcus temporalis superior significantly decreased during training, but only for the T+ group. The results suggest that there is a short-term, plastic reorganization of cortical representations specifically for the trained frequencies.

Auditory reafferentation by cochlear implants (CI) offers a unique opportunity to study longer-term auditory plastic changes taking place at up to the supra- or polymodal organizational level.³⁶ One functional magnetic resonance imaging study investigated the impact of early auditory deprivation and use of a visuospatial language (American sign language (ASL)) on the organization of neural systems important in visual motion processing by comparing hearing controls with deaf and hearing native signers.³⁷ Participants monitored images of moving dots under different conditions of spatial and featural attention. Recruitment of the motion-selective brain visual-processing area, known as MT in hearing controls, was greater when attention was directed centrally and when the task was to detect motion features, confirming previous reports that the motion network is selectively modulated by different aspects of attention. More importantly, marked differences in the recruitment of motion-related areas as a function of early experience were observed. First, the lateralization of MT was found to shift toward the left hemisphere in early signers, suggesting that early exposure to ASL is associated with a greater reliance on the left MT. Second, whereas the two hearing populations displayed more MT activation under central than peripheral attention, the opposite pattern was observed in deaf signers, indicating enhanced recruitment of MT during peripheral attention after early deafness. Third, deaf signers (but not subjects with

normal hearing), displayed increased activation of the posterior parietal cortex, supporting the view that parietal functions are modified after early auditory deprivation. Finally, attention to motion lead to enhanced recruitment of the posterior superior temporal sulcus only in deaf signers, establishing for the first time in humans that this polymodal area is modified after early sensory deprivation.

Imaging drug responses

The ability to monitor changing responses of subjects over several examinations makes fMRI potentially attractive for studying the effects of drugs. Cholinergic blockade is known to attenuate conditioning-related neuronal responses in the human auditory cortex. One recent study investigated the effects of cholinergic enhancement on experience-dependent responses in the auditory cortex.³⁸ The cholinesterase inhibitor physostigmine, or a placebo control, were continuously infused into healthy young volunteers, during a conditioning protocol conducted while fMRI data were being acquired. Volunteers were presented with two tones, one of which (CS+) was paired with an electrical shock, while the other was always presented without the shock (CS-). Conditioning-related fMRI activations were found in the left auditory cortex during placebo administration, but not with physostigmine. Analysis showed that this absence of conditioning-related activation with physostigmine administration was due to enhanced responses to CS- with physostigmine relative to placebo. The study report concluded that increases in cholinergic activity in the auditory cortex enhances processing of behaviourally irrelevant stimuli and that attenuates differential conditioning-related cortical activations.

CONCLUSIONS

Functional magnetic resonance imaging is already a major tool for cognitive neuroscience research. Studies can be performed on single subjects and in all current high-field MRI systems. With a growing appreciation for interpretation of the data, fMRI can also be expected to provide new clinical strategies for establishing diagnosis and prognosis and in treatment monitoring.

KEY POINTS

- Functional magnetic resonance imaging is currently the most commonly used functional brain imaging technique.
- With blood oxygenation level dependent fMRI, image contrast arises as a consequence

of the higher ratio of oxy- to deoxy-haemoglobin in local capillaries and draining venules with brain activity.

- Functional magnetic resonance imaging thus has a spatial (approximately 1–10 mm) and temporal resolution determined by the haemodynamic changes accompanying neuronal activity.
- Results should be interpreted primarily in terms of synaptic activity, rather than neuronal firing directly.
- Coupling between the neuronal and haemodynamic changes is complex and BOLD fMRI provides a measure of only relative synaptic activity.
- Applications of fMRI are growing rapidly and potentially have relevance to several aspects of otolaryngology.

Best clinical practice

A rigorous evaluation of fMRI as a tool for clinical decision-making has not been performed. While encouraging preliminary evidence has been presented in applications such as localization of functional tissue and lateralization of language and memory activity in preoperative surgical planning, there is little information with which to judge the validity and informativeness of data outside specific research contexts. However, the techniques are promising in several areas and active, clinically based research to test the possible utility in decision-making should be encouraged.

At this point, fMRI may be best regarded as experimental in a clinical context and the data derived from it should not be used independently to provide primary information for clinical decision-making.

Current deficiencies and suggestions for future research

There are several areas of current research that should provide the new clinical imaging strategies of the future. Some of these can be highlighted here to give a vision of what is to come.

MRI is highly versatile and can be used to generate contrast relevant to brain function based on phenomenon other than perfusion or BOLD. It may be possible to detect local distortions in MRI signal induced by the transient magnetic fields generated with neuronal depolarization, for example. New approaches to analysis of fMRI are addressing the problem of developing more

accurate models for the haemodynamic response. The better this is defined, the greater the potential sensitivity of the method. Several research groups are working to develop approaches that make no assumptions about the timing or nature of the haemodynamic response. Successful work in this area would allow brain activity to be defined independent of information regarding stimuli or behaviour. These developments and rapidly growing experience are fuelling an increasingly confident application of the technique to complex clinical problems, such as those related to understanding decision-making, motivation and emotion, as well as more sensitively studying changes in brain functions over time.

SEARCH STRATEGY

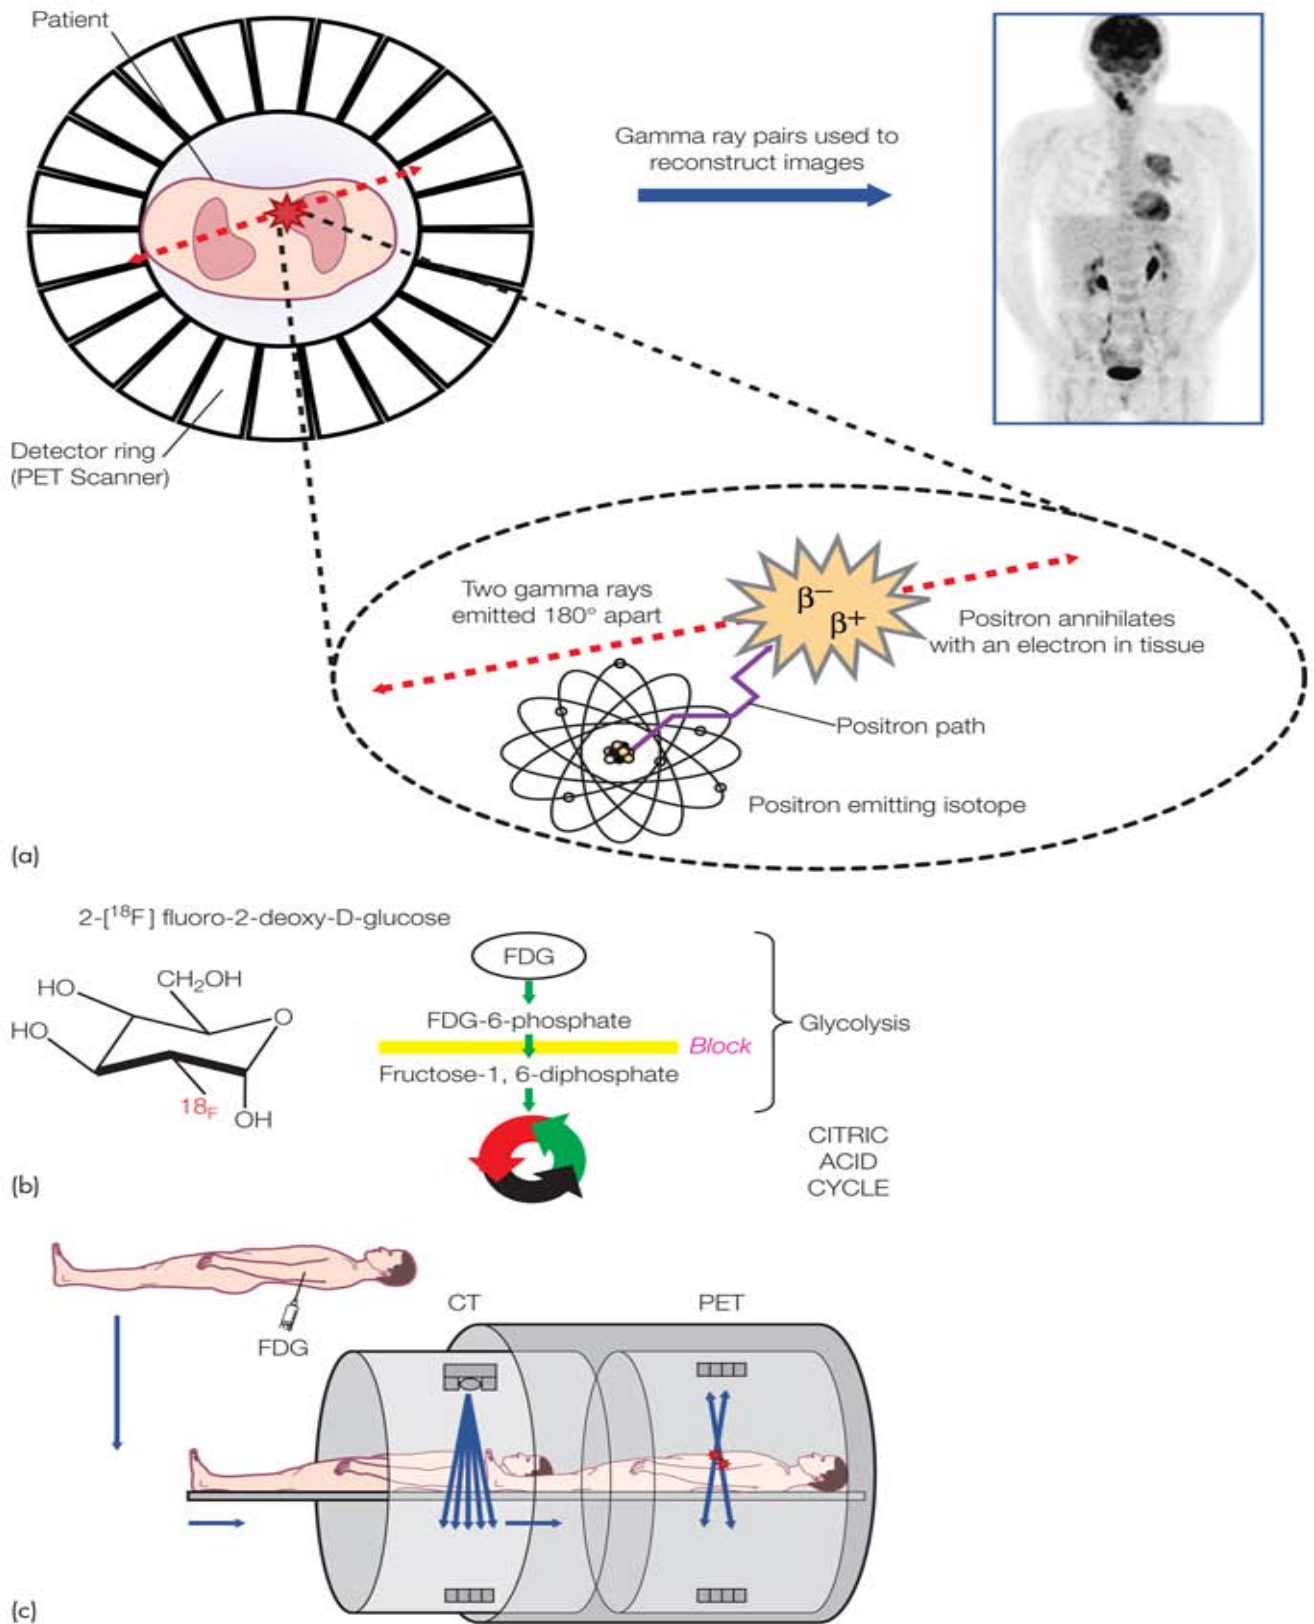

This chapter is supported by literature obtained by electronic searches of four biomedical databases (Medline, Embase, Cochrane Library, PubMed) using combinations of key words including PET, PET-CT, integrated PET/CT, FDG, positron emission tomography, tomography emission computed, fluoro-deoxyglucose F18, head and neck, cancer, thyroid cancer, staging, nodal metastases, occult primary, recurrence, surveillance, coincidence imaging and gamma camera. Studies were also sought from hand searches of head and neck surgery and other relevant journals, and scanning the reference lists of relevant articles. In this discussion, PET refers to a full ring bismuth germinate PET system.

PRINCIPLES OF PET

Computed tomography (CT), magnetic resonance (MR) and ultrasound produce anatomical images, whereas positron emission tomography (PET) provides a means of identifying pathology based on altered tissue metabolism. This functional imaging technique relies on a radioactive molecule (radiotracer) that decays with positron emission. The radiotracer is given intravenously to the patient and is taken into cells. The cell recognizes it as being 'foreign' and as a consequence it is trapped early in its metabolic pathway. Malignant cells trap more radiotracer compared with nonmalignant cells. The local radiotracer concentration can be measured *in vivo* since

these unstable radiotracers decay by positron emission. Positrons travel a short distance in tissue before colliding with electrons. When they collide, the annihilation reaction results in two photons also known as gamma rays of 511 kilo electron volts (keV) each emitted at approximately 180° to each other. The photons are detected by opposing detectors. A computer reassembles these signals into images that represent radiotracer uptake in the part of the body scanned (Figure 54.1a,b).

One of the main strengths of PET is the ability to perform quantitative studies. Absolute quantification is not often carried out in clinical practice as it is complicated to obtain and can demand direct arterial blood sampling. The standardized uptake value (SUV),

(b) Schematic representation of FDG metabolism. (c) Schematic representation of scanning with integrated PET/CT. The radiation burden is equivalent to two whole body diagnostic CTs. The CT is usually obtained using a low-voltage technique with no intravenous contrast given, but it is of diagnostic quality for detecting pulmonary metastases. Courtesy of Dr Bal Sanghera, Mount Vernon Hospital.

which provides a semiquantitative index of radiotracer uptake is widely used in clinical PET:

$$\frac{\text{Tracer uptake (MBq/mL)}}{\text{Administered activity (MBq)/(patient weight (kg) \times 1000)}}$$

PET images lack anatomical detail, which can be overcome by combining PET with CT/MR using software techniques (registration). With 2-[¹⁸F] fluoro-2-deoxy-D-glucose (FDG), these techniques are most robust in the cranium, extracranial head and neck and pelvis.¹

Depending on the radiotracer used, different aspects of tissue metabolism can be measured, such as distribution of blood flow, oxygen utilization and protein synthesis. The overwhelming majority of clinical studies are in conjunction with an analogue of glucose, 2-[¹⁸F] fluoro-2-deoxy-D-glucose, which reflects glucose metabolism. Cancer cells have a greater avidity for glucose than normal cells. Otto Warburg and colleagues² made this observation in the 1920s. FDG can be used to exploit the differences in glucose metabolism between cancer cells and normal cells.

2-[¹⁸F] fluoro-2-deoxy-D-glucose-positron emission tomography (FDG-PET) has been used effectively for imaging of a variety of malignancies including breast, lung, colorectal, oesophageal cancer, brain tumours, malignant melanoma and lymphoma.³ Seifert and others demonstrated that head and neck cancers take up FDG, an observation which was subsequently confirmed by other studies.⁴

SQUAMOUS CELL CARCINOMA

Primary disease

STAGING

FDG-PET can detect the majority of clinically visible primary tumours.^{1,5} The ability of FDG-PET to detect clinically visible lesions is of limited clinical use, but can be useful for more precisely delineating the primary tumour where submucosal extension of disease is a feature, such as in post-cricoid carcinoma and tracheal carcinoma (Figure 54.2).

Drawing from the cumulative results of three studies which included 2004 nodes correlated with resection specimens, FDG-PET had a sensitivity of 90 percent (200/222), specificity 94 percent (1666/1782), positive predictive value (PPV) 63 percent (200/316), negative predictive value (NPV) 99 percent (1666/1688).^{6,5,7} With regard to 'neck sides', from the summed data of 280 neck dissections, FDG-PET had a sensitivity of 82 percent (96/117), specificity 80 percent (130/163), PPV 74 percent (96/129), NPV 86 percent (130/151) and accuracy 81 percent (226/280).^{5,7,8,9,10,11} Encouragingly,

Figure 54.2 A 59-year-old man with a post-cricoid SCC. MR suggested more extensive disease than suspected on clinical assessment. (a) Sagittal T1-weighted MR scan demonstrates an intermediate signal intensity mass in the post-cricoid region (arrowhead). (b) FDG-PET sagittal image shows the post-cricoid SCC (arrowheads). The extent of disease seen on FDG-PET was in agreement with the MR. B, physiological uptake in brain; UB, normal activity in bladder as FDG is excreted via the kidneys through the bladder.

FDG-PET detected contralateral neck metastases, but it is unclear how many of these were unsuspected prior to FDG-PET.^{6, 5, 7, 8, 12} All studies show a high NPV but this may be overestimated because not all patients had radical neck dissections. Preliminary results suggest that FDG-PET is at least as effective as conventional imaging, if not more so, at staging the neck.^{6, 5, 7, 8, 9, 13, 14} However, the additional information gained from FDG-PET compared with other imaging is unclear. In a prospective study which included 100 neck sides, colour-coded duplex ultrasonography (CCDU) was as accurate as FDG-PET for detecting nodal disease, with similar sensitivity and specificity.¹⁴ In accessible areas, namely levels I–VI, CCDU especially when combined with fine needle aspiration cytological examination (FNAC) may well prove to be as accurate as FDG-PET.¹⁵ However, CCDU will not detect retropharyngeal and mediastinal nodal disease.

What is clear from the literature is that FDG-PET cannot consistently detect subclinical disease and so does not obviate elective treatment of the neck.^{5, 7, 11, 12} It can have a role to play in those patients with equivocal nodal disease following conventional assessment. In patients with high risk of neck metastases, a positive scan will be highly indicative of neck nodal disease and the detection of contralateral or bilateral nodal disease can be particularly useful in this group of patients (Figure 54.3). Conversely, a patient with low risk of nodal metastases and a negative FDG-PET is most unlikely to have neck nodal disease (Figure 54.4).

In patients with advanced disease in the head and neck (stage III/IV), FDG-PET is potentially useful for detecting occult mediastinal nodal disease.¹⁶ Distant metastatic disease in patients presenting with head and neck cancer is unusual and limits the use of FDG-PET as a screening test. However, it may have a role in those patients with a high risk of distant metastases, e.g. locally advanced nasopharyngeal cancer.¹⁷

Detection of synchronous malignancies

The cumulative incidence of a second malignancy following head and neck cancer is up to 15 percent. Fewer than half will have a detectable synchronous primary malignancy and almost half will be detected by a thorough clinical assessment and a further number by chest CT. So, the pick-up rate of FDG-PET at the time of primary diagnosis is likely to be 2–3 percent, substantiated by one study of 56 patients where it detected one occult lung cancer, a case finding yield of 2 percent.¹⁸ FDG-PET has the advantage over other imaging modalities as it can scan the entire body for disease, which is often not possible with other techniques. The low rate of synchronous malignancy perhaps does not justify routine screening.

OTHER COMMENTS

Pilot studies suggest that pretreatment FDG-PET can be useful as an independent predictor of treatment response and also subsequent prognosis.^{19, 20, 21, 22, 23} If these results can be substantiated, it will allow the clinician to identify patients where a more aggressive treatment approach should be considered. [***/**]

Recurrent/residual disease

PRIMARY SITE

A recent survey of the literature identified 10 relevant studies where FDG-PET was used to assess recurrent/residual disease and where there was pathological confirmation of the positive FDG-PET findings and follow-up of at least six months for negative FDG-PET results. The sensitivity of FDG-PET varied between 71 and 100 percent, the specificity between 85 and 100 percent, PPV between 64 and 100 percent, NPV between 60 and 100 percent and accuracy between 78 and 100 percent.^{13, 14, 24, 25, 26, 27, 28, 29, 30, 31} The varying results are a reflection not only of the small number of patients in each study, 8 to 43 patients, but also the various different clinical situations where FDG-PET was used.

The challenging clinical issue is the detection of recurrent disease when it is still amenable to curative salvage treatment. Prospective studies that have focussed on patients who become symptomatic during follow-up show FDG-PET to be effective and superior to CT/MR in this area.^{13, 14, 24, 29, 30} Cumulatively, these studies included 215 patients, 218 FDG-PET scans and an analysis of 226 anatomical sites. FDG-PET distinguished between recurrent disease and treatment sequelae at the primary site with an overall sensitivity of 88 percent (102/116), specificity 83 percent (91/110), PPV 85 percent (102/121), NPV 87 percent (91/105) and accuracy 85 percent (193/226).^{13, 14, 24, 25, 26, 27, 28, 29, 30, 31} In a group of 38 patients where FDG-PET was used to differentiate between post-irradiation laryngeal recurrent cancer from laryngeal oedema, it achieved a correct diagnosis in 79 percent and was superior to CT (61 percent) and clinical assessment (43 percent).³⁰

FDG-PET is potentially useful as a surveillance tool for patients with high risk of relapse. In one study, in 10/10 patients FDG-PET accurately detected the presence of recurrent disease despite negative or equivocal MR and indeterminate clinical examinations.²⁵ In a prospective study of 30 advanced head and neck cancer (stage III/IV) patients with FDG-PET performed 2 and 10 months after completion of therapy, FDG-PET detected all 16 recurrences which occurred during the first year post-treatment. In five of these 16 patients, FDG-PET was the only technique which detected the recurrences, four at the primary site and one patient with lung metastases.³²

Figure 54.3 A patient referred for assessment of supraglottic laryngeal squamous cell carcinoma with equivocal nodal disease on conventional evaluation. Clinical assessment suggested contralateral nodal disease not confirmed by MR and ultrasound-guided fine needle aspiration cytology examinations. FDG with integrated PET/CT demonstrated (a) the primary site (arrow); (b) ipsilateral neck nodal disease (arrow); and also (c) contralateral neck nodal disease (arrows). (d) The contralateral neck nodal disease, which corresponded to a cluster of three subcentimetre nodes on CT, was subsequently confirmed by neck dissection.

Following radiotherapy, the minimum interval that should be allowed before performing FDG-PET for evaluation of recurrent/residual disease has yet to be determined. In a group of 25 radiotherapy (RT) patients who were followed up between 4 and 11 months and where all failures were confirmed by pathological correlation, there were fewer false-negative results when FDG-PET was performed four months after RT compared with one month following RT.³³ In a series

of 44 consecutive patients there were no false-negative results, but a significant number of false-positive results when FDG-PET was performed 12 weeks or less following various treatments for recurrent/residual disease.³⁴ This is in contrast to our own experience of 11 patients with a high risk of recurrence where FDG-PET was performed eight weeks post-RT as part of a surveillance study. Of the nine negative studies, there was one possible false-negative result and no

(c)

Figure 54.4 A 33-year-old woman presented with a right level II node due to SCC. Conventional assessment including EUA with multiple biopsies and CT/MR did not identify the primary site. FDG with integrated PET/CT (a) shows the tonsillar SCC (arrow); (b) confirms the level II nodal mass (arrowhead) and also shows contralateral neck nodal disease (arrow); (c) corresponds to a node of normal size, short axis diameter of 8 mm, on the CT component of integrated PET/CT (arrow).

false-positive results; both patients with positive FDG-PET scans relapsed.

Recurrent/residual disease as a group show higher FDG uptake compared with sequelae of treatment. Semi-quantitative analysis, however, does not improve discrimination between active disease and post-treatment changes as there is considerable overlap of SUVs between these two groups.^{24, 35}

In clinical practice, FDG PET and now FDG with integrated PET/CT is routinely considered eight weeks or more following RT. A definitively positive scan should be taken as highly suspicious of disease as long as there is no infection. A negative scan is highly likely to represent absence of active disease, but still demands careful

surveillance as microscopic foci of active disease cannot be excluded. An equivocal scan requires biopsy in areas of FDG activity or an early repeat FDG-PET.

FDG-PET is more accurate than conventional methods for assessment of recurrent/residual disease, but false-positive and false-negative results occur and so must be used in the context of the overall assessment of the patient.^{24, 25, 26, 27, 28, 29, 31, 34, 35} A positive scan can influence a more aggressive biopsy approach and a negative scan a more conservative approach. In some instances it can be used to select sites for further biopsies in biopsy-negative patients with suspected recurrent/residual disease, thus increasing the yield of positive biopsies and avoiding unnecessary deep biopsies (Figure 54.5).

© Hodder Arnold / Scott-Brown 7E

Figure 54.5 A 62-year-old man, nine months after radical RT with curative intent for a T3 N1 laryngeal SCC. EUA, including multiple biopsies, did not show active disease. (a) Sagittal T1-weighted MR scan demonstrating an intermediate signal intensity mass in the supraglottic larynx. (b) Axial T2-weighted MR scan shows the mass to be predominately of low signal. (c) FDG-PET axial and (d) sagittal images shows intensive uptake in the laryngeal oedema consistent with recurrent disease (arrow), confirmed by further biopsies.

Furthermore, as in patients with primary disease, **FDG-PET will detect other unexpected cancers in some patients** (Figure 54.6). [***/**]

Post-treatment neck assessment

Two retrospective reviews, with 34 patients in one study and 36 patients in the other, found FDG-PET had a sensitivity of 100 and 93 percent, specificity of 89 and 77 percent, PPV 70 and 72 percent, NPV 100 and 94 percent, respectively. Both studies suggested FDG-PET to be superior to CT/MR.^{26, 27} These results are in agreement with a prospective study where FDG-PET identified recurrent nodal disease in all eight patients seen with suspected nodal recurrence who subsequently had histologically proven disease. In this series, the

sensitivity and specificity of FDG-PET was 100 percent, compared with CT/MR (75 and 80 percent, respectively) and clinical evaluation (100 and 60 percent, respectively).¹³ These **results suggest that FDG-PET is a potentially useful tool for assessing recurrent disease in the post-treatment neck and is an area that deserves further attention.** [***/**]

Preliminary results show that FDG PET is accurate for detection of residual neck disease when performed at least eight weeks after chemoradiotherapy.^{36, 37, 38, 39} There is considerable interest in the use of FDG with integrated PET/CT for the detection of residual disease in the neck in patients with advanced (N2 and N3) nodal metastases following chemoradiotherapy. A multicentre UK trial has recently been funded by the department of health to test the hypothesis that FDG with integrated PET/CT guided watch and wait is a valid alternative to the current

Figure 54.6 A 63-year-old man with clinical suspicion of recurrence at the surgical bed at the primary site. Direct inspection including biopsies, CT and MR did not provide a definitive diagnosis. FDG with integrated PET/CT demonstrated (a) recurrent disease within the surgical bed (arrows); (b) and (c) uptake in the rectum suspicious of rectal carcinoma (arrowheads), confirmed by subsequent colonoscopy and biopsies.

||b.

practice of planned neck dissection in this group of patients. Results from this study are awaited with interest.

OCCULT PRIMARY TUMOURS

The cornerstone for investigating this group of patients is with examination under anaesthesia (EUA), including multiple biopsies and CT/MR. As such, FDG-PET can only be justified if it can detect more primary sites following these investigations. The various studies which have investigated FDG-PET in this setting have shown, without exception, that FDG-PET can detect more primary sites

compared with conventional assessment.^{40, 41, 42, 43, 44, 45, 46}

In a study of 27 patients which included 21 squamous cell carcinomas (SCC) and undifferentiated carcinomas, FDG-PET showed 28 percent more histologically proven primary sites.⁴⁵ Our own experience is similar with FDG-PET detecting 29 percent more pathologically confirmed primary sites.⁴⁶ In four other studies, with 7–14 patients with occult SCC or undifferentiated carcinoma in each study, FDG-PET detected between 8 and 42 percent more histologically verified primary sites compared with conventional work up.^{40, 41, 42, 43, 44} Some of the occult primaries detected were lung cancers in patients who did not have chest CT; it is unclear how many of these lung

cancers would have been detected by CT. Excluding the lung cancers, FDG-PET detected up to 20 percent more primary sites.^{40, 41, 42, 43, 44}

Well-documented false-positive results are unusual in the literature: there were 15 (9 percent) clinically or histologically verified cases from a cumulative total of 173 head and neck sites (nasopharynx, 2; tonsil, 5; tongue base, 3; submandibular gland, 1; oral cavity, 1; thyroid, 2; epiglottis, 1) and a further five (2 percent) in the lungs where no tumour was identified at subsequent bronchoscopy or CT.^{27, 40, 41, 42, 43, 44, 45, 46, 47, 48} One study is at variance with a false-positive result of 46 percent (6/13);⁴³ the authors suggest that it was possible that the biopsy was in error and that the true PPV of the technique was underestimated. In one study, all 17 patients including the three patients where FDG-PET showed a primary site which was not subsequently confirmed, were treated on the basis of the FDG-PET result. No other primary head and neck tumour developed during subsequent follow-up in any of the patients.⁴⁶ This result supports the speculation that FDG-PET may be more specific than the current figures indicate. Further clarification may be available with long-term follow-up of larger groups of patients.

Inflammatory pulmonary lesions including granulomas and abscesses and recent biopsy can result in false-positive FDG-PET.^{40, 42} Dental caries and benign thyroid and salivary gland nodules are recognized causes of intense FDG uptake and so do not usually cause a diagnostic dilemma. We have found that tonsillectomy can cause potential confusion, not on the side of surgery but on the contralateral side, where normal tonsillar uptake in the remaining tonsil can mimic a malignancy.

Considering all the studies with false-negative results reported, there was a cumulative total of over 127 patients and only 10 (8 percent) false-negative results confirmed at histology or subsequent follow-up: tongue carcinoma, 3, including 2 base of tongue carcinomas; tonsillar carcinoma, 2; nasopharyngeal cancer, 1; lung cancer, 2; mesothelioma, 1; and gastric carcinoma, 1.^{27, 40, 41, 42, 43, 44, 45, 46} The ability to detect cancers less than 1 cm in diameter with FDG-PET is currently unclear. Using attenuation corrected scanning, FDG-PET showed a 4-mm base of tongue SCC in one study.⁴⁰ Even in retrospect, a further study failed to show a 7-mm pharyngeal wall SCC with attenuation correction scanning.⁴⁶

Most studies report that in the majority of patients with an occult primary tumour after staging which includes FDG-PET, no head and neck primary tumour will emerge after treatment during subsequent follow-up.^{40, 41, 42, 43, 44, 45, 46, 47, 48}

FDG-PET can influence the therapeutic plan further in up to 59 percent of patients.^{41, 42, 44, 45, 46, 47, 48} It can alter management by not only identifying the primary site, but also other occult sites of disease including bony metastases, mediastinal nodal disease and synchronous carcinomas at other sites.^{40, 45}

Biopsies carried out after FDG-PET can improve the number of occult primaries detected compared with EUA with speculative biopsies.^{40, 41, 42, 45} [***/**]

OTHER MALIGNANT TUMOURS

FDG-PET is of limited value for the preoperative assessment of thyroid nodules as both malignant and benign thyroid lesions can be equally avid for FDG. However, it can have a role in the assessment of the post-treatment patient. In a study of 24 patients with treated differentiated papillary and follicular thyroid cancer, the metastases had an alternating pattern of uptake with ¹³¹-iodine and FDG. Either some ¹³¹-iodine uptake combined with low FDG trapping or no ¹³¹-iodine uptake combined with high FDG trapping.⁴⁹ The hypothesis was that persistent iodine metabolism is consistent with better cell differentiation, while the loss of this ability together with increased glucose metabolism is consistent with dedifferentiation.⁴⁹ Several reports have demonstrated the value of FDG-PET in treated papillary and follicular thyroid cancer patients who have suspected recurrent disease with a high thyroglobulin levels and negative ¹³¹-iodine scan.^{49, 50, 51, 52, 53} In a retrospective review, FDG-PET was found to be useful in 64 percent (39/61) of patients who had an elevated thyroglobulin and negative ¹³¹-iodine scan with a PPV of 83 percent (34/41) and an NPV of 25 percent (5/20). Furthermore, true positive FDG-PET findings correlated positively with increasing thyroglobulin levels.⁵² In a study of 18 patients with elevated thyroglobulin levels FDG-PET localized occult disease in 71 percent (12/17) of patients who subsequently had confirmation of disease, mainly unsuspected neck and chest nodal disease; FDG-PET was of much more limited value in patients with normal thyroglobulin levels.⁵³

The overall accuracy of FDG-PET in this setting is unclear. In all published studies, many lesions were not verified histopathologically and in most studies the follow-up period after FDG-PET was unclear. The incremental improvement afforded by FDG-PET over other imaging is also uncertain. Various studies show FDG-PET has an advantage over ¹³¹-iodine in its ability to detect more nodal disease in the neck and in the mediastinum.^{53, 54, 55, 56} With regard to the neck, however, none of these studies systematically compared neck MR and ultrasound with FDG-PET. In one survey, minimal cervical nodal disease present in three patients not detected by ¹³¹-iodine and FDG-PET was shown on ultrasound.⁵³ In most of the patients where FDG-PET detected mediastinal nodal disease, a comparison with CT (chest) was not made. In the literature, FDG-PET demonstrated lung metastases which were not iodine avid, but these same studies showed that CT was superior to FDG-PET in this area (Figure 54.7).^{53, 55}

Figure 54.7 A 38-year-old man who presented with elevated thyroglobulin after total thyroidectomy and 131-iodine ablation for papillary thyroid cancer. (a) Whole body 123-iodine scan showed no active disease. (b) FDG with integrated PET/CT shows the nodal recurrence corresponding to (c) normal sized nodes on CT (arrow). Surgery and histological examination confirmed retropharyngeal nodal disease.

(c)

Thallium and hexakis (2-methoxyisobutyl-isonitrile) technetium-99m (MIBI) have been proven to be useful radiopharmaceuticals as alternatives to 131 -iodine in the follow-up of differentiated thyroid cancer. A retrospective multicentre study evaluated the use of 131 -iodine, FDG and MIBI in the follow-up of 222 such patients. FDG was more sensitive than iodine 131 and MIBI, 75, 50 and 53 percent respectively with no compromise in specificity, 90, 99 and 92 percent, respectively.⁵¹

FDG-PET can detect metastases from Hurthle cell carcinoma and anaplastic carcinoma.^{53, 57} Its clinical value in these tumours is currently unclear.

With medullary thyroid cancer, preliminary results suggest FDG-PET to be an accurate technique for detecting metastases and recurrent disease. The largest study in the literature, a German multicentre retrospective survey, reviewed 100 FDG-PET studies performed on 85 patients. The results of the FDG-PET were compared with 46 indium-111 pentetreotide (SMS) studies, 33 pentavalent technetium dimercaptosuccinate acid (DMSA) scans, 8 hexakis (2-methoxyisobutyl-isonitrile) technetium-99m (MIBI) scans, 64 CT and 37 MR. One hundred and eighty-one lesions were identified by at least one technique; FDG-PET detected the majority of lesions with a lesion detection probability of 68 percent compared with 25 percent for SMS, 29 percent for DMSA, 6 percent for MIBI, 53 percent for CT and 58 percent for MR. In the 55 lesions confirmed histologically, FDG-PET had the highest overall accuracy with a sensitivity of 78 percent and specificity of 79 percent; MR had a slightly higher sensitivity of 82 percent, but a specificity of 67 percent and MIBI had a specificity of 100 percent, but a sensitivity of only 25 percent.⁵⁸

In one published report of postoperative parathyroid carcinoma, FDG-PET provided more accurate information compared with other imaging.⁵⁹

FDG-PET cannot reliably distinguish between malignant and benign major salivary gland tumours as both can be equally FDG avid. It can, however, be useful for distinguishing active disease from sequelae of treatment.

FDG-PET is effective for detecting lymphoma except low-grade non-Hodgkin's lymphoma and extranodal marginal zone B-cell lymphoma, which are not consistently FDG avid.^{60, 61}

Head and neck malignant melanomas, sarcomas and paragangliomas have been shown to be FDG avid.^{62, 63} FDG-PET can be useful in these rare head and neck tumours for detecting occult sites of disease, especially when more disease is suspected than can be accounted for by conventional assessment, provided the known sites of disease are FDG avid (Figure 54.8). [***/**]

INDETERMINATE PULMONARY LESIONS

Cancer patients with indeterminate pulmonary lesions following full clinical and radiological assessment can

Figure 54.8 A 49-year-old man presented with left neck nodes due to high-grade non-Hodgkin's lymphoma (NHL). He had systemic symptoms but conventional assessment showed disease that was localized to the left neck. (a) FDG-PET coronal slice demonstrates disease in the neck (arrowheads) and also in the mediastinum (hollow arrowhead) and axilla (arrow). The patient's management was changed from localized RT to the neck to chemotherapy. (b) Following chemotherapy, the FDG abnormalities in the neck, axilla and mediastinum resolved. Increased uptake is seen along an infected Hickmann line (arrowheads).

present a diagnostic dilemma to the surgeon, and head and neck cancer patients are no exception. Accurate characterization of the pulmonary abnormality can alter treatment plan. FDG-PET has been shown to be an accurate noninvasive test for the diagnosis of pulmonary lesions (Figure 54.9). A metanalysis of the data from 40 studies showed FDG-PET has a sensitivity of 96.8 percent and specificity of 77.8 percent.⁶⁴ Abscesses and granulomas including those due to sarcoid, tuberculosis (TB), anthracite and fungus (asperilloma, blastomycosis, coccidiomycosis, cryptococcosis, histoplasmosis) can mimic malignant lesions.⁶⁵ False-negative FDG-PET results are very unusual, although bronchoalveolar carcinoma, highly differentiated neuroendocrine carcinoma and adenocarcinoma, especially within a scar, have been reported to cause confusion.⁶⁵ Lesions smaller than 1 cm across can be detected by FDG-PET, but false-negative results do occur and so a negative scan must be interpreted with caution.⁶⁵ [***/**]

ALTERNATIVE IMAGING METHODS FOR FDG UPTAKE

Owing to the high costs and limited availability of full ring bismuth germinate PET systems, alternative methods of imaging 511 keV photons of positron emitters have been sought. To this end, partial ring bismuth germinate systems, such as the ECAT advanced rotating tomograph (ART), scanners with six positron-sensitive sodium

Figure 54.9 A 54-year-old man with clinical suspicion of recurrence of oropharyngeal cancer. CT and MR did not provide a definitive diagnosis. (a) FDG with integrated PET/CT demonstrated recurrent disease in the post-treatment neck (arrow); and (b), (c) and (d) uptake in the right hilum of the lung suspicious of a bronchogenic carcinoma (hollow arrowhead), confirmed by subsequent bronchoscopy and biopsies.

iodide detectors and dual-headed gamma cameras operating in coincidence have been developed. These systems are less sensitive compared with full ring dedicated PET systems. Nevertheless, their performance may be adequate in the specific clinical settings.

Stokkel and colleagues, in a retrospective review of 54 consecutive SCC patients, found FDG dual-head PET a valuable tool for staging the neck.⁶⁶ In a prospective study of 48 patients with suspected recurrent laryngeal or hypopharyngeal cancer, the results obtained with FDG dual-headed PET was comparable with those from studies using full ring PET.⁶⁷ Similar results were obtained in one study using a sodium iodide detector system and a partial ring PET in another; in both, FDG was superior to CT/MR.^{68, 69}

In three studies, non-full ring PET systems detected 28–73 percent more occult head and neck primary tumours compared with conventional imaging. It is unclear how many of the occult malignancies would have been detected by EUA and multiple biopsies, as FDG was performed prior to EUA in all patients studied.^{69, 70, 71}

With regards to thyroid cancer, several pilot studies have shown the feasibility of FDG dual-head PET for detecting recurrent disease in patients with elevated thyroglobulin and negative ¹³¹I-iodine scan.^{72, 73}

Despite these encouraging preliminary reports for the use of non-full ring PET for the assessment of head and neck cancer patients, there is now very limited interest in the use of this technology with the advent of combined PET-CT scanners.

RADIOTRACERS OTHER THAN FDG

Carotid artery resection may occasionally offer a chance of cure in patients with advanced head and neck cancer. [15-O] H₂O PET has been used a rapid quantitative means of determining cerebral blood flow prior to carotid artery resection in this group of patients.⁷⁴

Beyond clinical studies, PET provides the unique opportunity to assess specific biological characteristics of head and neck cancer with minimal disturbance of tumour physiology. Hypoxic areas in head and neck tumours have been successfully evaluated with PET using radiolabelled nitroimidazole compounds including fluorine-18 fluoromisonidazole (FMISO) and fluorine-18 fluoroerythronitroimidazole (FETNIM).^{75, 76} Thymidine labelled with 11-carbon, [methyl-11C] thymidine and L-[methyl-11C] methionine (11-C methionine) have been developed to enable the measurement of the proliferative capacity of head and neck tumours.^{77, 78} Chao and others demonstrated the feasibility of using Cu(II)-diacetyl-bis-N4-methylthiosemicarbazone (Cu-ATSM), a hypoxic marker, for planning intensity modulated radiotherapy.⁷⁹

NONONCOLOGICAL APPLICATIONS

FDG-PET is potentially a useful tool in the assessment of cochlea implants and their pattern on stimulation of the central nervous system. A pilot study using FDG-PET and [15-O] H₂O demonstrated that the primary auditory cortex does not develop normally in prelingually deaf subjects, but that in post-lingually deaf subjects this is not so and the primary auditory cortex may be reactivated by cochlear implant after many years of deafness.⁸⁰

INTEGRATED PET/CT

Positron emission tomography is limited by the imprecise localization of radiotracer. Software image fusion is labour-intensive and is usually unsuccessful unless data are acquired prospectively. Furthermore, accurate software registration is generally only valid for FDG-PET. The advantages of integrated PET/CT include superior localization of lesions and better distinction between physiological uptake and pathology. With PET/CT, CT is acquired followed by PET. Using CT for attenuation correction also means shorter scanning times; 30 minutes compared with 60 minutes with standard FDG PET. PET/CT should augment the information provided by PET; it will more accurately localize the occult primary in the oropharynx. In patients with suspected recurrence of thyroid cancer, the CT component will detect pulmonary metastases not identified on FDG and in other patients more precise anatomical localization of active disease within treatment sequelae will influence the treatment plan.^{81, 82, 83}

KEY POINTS

- The use of FDG-PET in head and neck cancer is supported by data from observational and nonrandomized studies. There are no randomized controlled trials available.
- The body of evidence shows that FDG-PET can contribute to more accurate assessment of patients with head and neck cancer, including improved staging of the neck, detection of recurrent/residual disease, detection of the occult primary and detection of occult disease in treated differentiated thyroid cancer.
- Beyond FDG, PET provides the unique opportunity to assess specific biological characteristics of head and neck cancer with minimal disturbance of tumour physiology.
- Integrated PET/CT should improve the accuracy of FDG PET.

Best clinical practice

FDG-PET, and now FDG with integrated PET/CT, is not necessary for all patients with head and neck cancer. For most, clinical assessment complemented by conventional imaging will give all the necessary information for planning treatment. However, FDG with integrated PET/CT can be useful for a selected minority. With the present state of knowledge, the following are recommended as current indications of FDG with integrated PET/CT:

- ✓ SCC patients with
 - equivocal nodal disease following conventional assessment, especially if the nodes in question are not accessible to ultrasonography or ultrasonography with FNA has not provided a conclusive result;
 - suspicion of recurrent/residual disease and equivocal clinical or radiological assessment.
- ✓ Patients with occult primary tumours: FDG with integrated PET/CT should be considered prior to EUA and after full clinical assessment, laryngoscopy/fibreoptic endoscopy and CT/MR fail to show a primary tumour. This investigation algorithm provides the best opportunity for detecting the occult primary, whilst minimizing misleading results.
- ✓ Post-treatment papillary and follicular thyroid cancer patients with elevated thyroglobulin and negative 131-I scan.
- ✓ Patients with clinical suspicion of more disease than conventional assessment demonstrates.
- ✓ Patients where resectability is in doubt.

- ✓ Patients with indeterminate lung lesions which are not accessible to precutaneous biopsy or where a pneumothorax would be particularly hazardous. [Grade C/D]

Deficiencies in current knowledge and areas for future research

- Large prospective comparative studies of FDG with integrated PET/CT with state-of-the-art ultrasound (neck) for patients referred for assessment of primary disease and equivocal necks following conventional assessment.
- Prospective studies evaluating FDG with integrated PET/CT as an early predictor of response to treatment and as an independent prognostic factor for head and neck SCC.
- Large prospective studies evaluating the value of FDG with integrated PET/CT as a surveillance tool in head and neck SCC patients with high risk of recurrence.
- Prospective comparative studies including MR and state-of-the-art neck ultrasound, CT (chest) and FDG with integrated PET/CT for the assessment of patients with treated differentiated thyroid cancer, elevated thyroglobulin and negative whole body ¹³¹I scan.
- Integrated PET/CT studies with hypoxic and cell proliferation markers for evaluating the biology of malignant head and neck tumours.

ACKNOWLEDGEMENTS

I am very grateful to my clinical oncology and head and neck surgery colleagues with whom I work closely, especially Professor Michele Saunders, Mr Roy Farrell, Dr Katherine Lemon, Dr Kate Goodchild. I also gratefully acknowledge Dr Jane Chambers for her useful critical comments.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words image-guided surgery, endoscopic sinus surgery and skull base surgery.

INTRODUCTION

Image-guided surgery (IGS) has developed as a result of advances in computer science, digital scanning and image processing. It is a relatively new technology that provides surgeons with information before and during an operative intervention. IGS is an important part of modern surgical practice in disciplines that include neurosurgery, otorhinolaryngology, maxillo-facial and orthopaedic surgery. Synonyms for this technology include computer-aided surgery, navigational surgery and computer-guided surgery.

With this technology, magnetic resonance (MR), computed tomography (CT) or combined image data sets are used to create three-dimensional (3D) reconstructions of the operative volume. These 3D reconstructions can be used to plan surgery (surgical planning), practise a certain surgical procedure (surgical simulation) or to navigate during the surgical procedure (image-guided surgery). Computer-aided surgery is the umbrella term that is sometimes used to encompass all these processes.

BACKGROUND AND OVERVIEW

It has been possible to generate 3D models of a specific anatomical region from two-dimensional (2D) CT data sets for some time (**Figure 55.1**).¹ At the outset, these 3D models were used to make measurements, drive numerically controlled milling machines to create physical models and to view a patient's anatomy and disease process from every aspect.² The extraction of specific structural detail (segmentation) from the data became possible with the development of sophisticated image-processing software and the advantages of preprocessing data in this way became apparent very quickly. It was then only a matter of time before this technology was used to facilitate live surgery. In the operating theatre, images were presented to the surgeon as 2D slices within the three orthogonal planes of space, or as 3D reconstructions displayed on a 2D computer screen. Surgical tools were developed to enable the localization of anatomical features or to confirm the precise position of a pointer within the operative field.

Figure 55.1 3D reconstruction of CT image data showing the involvement of the skull base by an extensive chordoma (arrowed).

Surgeons appreciated that this information was particularly useful in those situations where the disease process or previous surgery has distorted the normal anatomy.³ Since then, alternative methods of image display have been developed that include image overlays on the surgical field visible through the operating microscope.⁴ These computer-generated images may be vector representations of previously segmented and preprocessed data. Alternatively, part of the 3D data set can be superimposed on the patient's anatomy, thus providing the surgeon with an extraordinary 'x-ray' type vision (**Figure 55.2**).⁵ Augmented reality is an allied area of research that has yet to fulfil its true potential, but will surely replace conventional IGS in the not too distant future.⁴

Preoperative imaging serves two distinct purposes. First, it is a diagnostic tool. Second, it is used to assess the extent of disease. By careful scrutiny of the images, the surgeon becomes familiar with the anatomy and surgical needs of his patient. The amount of preoperative imaging for complex cases has increased significantly over recent years. Surgeons no longer have to rely so much on their anatomical acumen and intuition in difficult situations. Nowadays, complex and thorough preoperative image processing removes some of the guess work in surgery and utilizes to the full all the information that is acquired. It is hoped that at the least this makes surgery safer and the training of future generations of surgeons better.

Figure 55.2 Vestibular schwannoma. (a) MR scan; (b) intraoperative view through the microscope with the segmented image data overlain on the operative scene.

Surgeons nowadays plan their approach using data obtained from various imaging modalities. Maxillofacial surgeons were among the first to make use of computers for surgical planning.⁶ They used 3D reconstruction of CT scans of the skull to drive a numerically controlled milling machine that produced prostheses for patients, precise replicas of their normal tissues. The outcome was better fitting prostheses and surgery that took a fraction of the time required by more traditional methods where the prostheses were hand-made during the operative process.⁶ Orthopaedic surgeons currently use 3D data sets to drive robots designed to perform accurate drilling of the femur or tibia during hip and knee replacements. Robots controlled by computers using patient specific 3D data sets are extremely accurate. The result is better fitting prostheses and fewer failures and morbidity for patients.⁷ Image-guided surgery, when used by trainee surgeons in endoscopic sinus surgery, improves surgical accuracy and reduces the risk of major intracranial or intraorbital

complications that might be caused by inexperience. It enhances surgical efficiency and accelerates the learning curve by reducing operative time while maintaining greater than 90 percent accuracy in identifying critical anatomical landmarks.⁸

In the sections that follow, we discuss the principles and elements of IGS so that the user can better understand the technology and jargon that accompanies it.

IMAGE RECONSTRUCTION

The creation of a 3D data set from 2D sections is performed by software using highly complex algorithms that are specific to the particular scanner and scanning protocol employed. Powerful computer workstations are required to run these software programs. This process is automated and requires little clinician input. It is important to consider and understand the various aspects of 3D reconstruction as it has a direct effect on accuracy and visualization.

The concept of slices

Conventional CT scan converts one-dimensional x-ray data into a 2D slice. This is referred to as a single image section and may be acquired along axial, coronal or other planes by changing the gantry angle. Tilting the gantry tilt is extremely useful as sections can be acquired that avoid predictable artifacts, for example those caused by dental restorations. Subtle changes to the gantry angle can also help show certain anatomical features better. Each individual section has a width known as a slice thickness, a factor that pertains to the width of the x-ray beam detector window used. Smaller width beams (windows) produce higher resolution 2D images.

Slices are spaced along the area to be scanned with an inter-slice distance that varies depending on the scanning protocol being used and on the size of the anatomical structure that is being imaged. Spiral and multi-slice CT scans are faster and expose the patient to less radiation than their traditional counterparts. They collect x-ray data in a helical fashion that is reconstructed later into 2D sections or indeed 3D volumetric voxel data sets. The resulting data set from a spiral CT scan may be reformatted along the sagittal, coronal or axial planes, as well as emulating any gantry tilt.

Pixels and voxels

Two-dimensional slice sections are composed of pixels which are the smallest picture elements. The more pixels in a certain distance, the better the resolution. Currently, the highest resolution available for both CT and MRI is 512×512 pixels per image. In a field that is 30×30 cm, this

gives a high definition picture, whereas in a large field this gives a low resolution. By convention, the image resolution is stated by the number of pixels in the x and y axis only and the size of the image field will not be actually defined.

Each pixel has a value ranging, in the case of the CT scan, from -1000 to 3096 . This is often referred to as Hounsfield units (HU). CT scans are calibrated such that the value of 0 equates to the density of water. By convention, high pixel values are displayed as white. The lower the value, the lower the density of the tissue and the darker the pixel would appear. Pixels are 2D, but it is possible to convert these picture elements into a 3D block. This 3D block is referred to as a voxel or a volumetric picture element. Voxels can be a cube or cuboid depending on the inter-slice distance.

Volume averaging

If a structure falls partially within a pixel, the true value of that structure will then be assigned a value less than the normal value of the structure. In the case of bone, which has a value of say 1000 HU, the value of a pixel that includes a part of that part of the bone will be much less, perhaps 500 . This is referred to as partial volume averaging and is a major problem in delineating where the edge of a structure should lie within a given image. Higher resolution images would overcome that problem to some extent. This is not always possible as higher x-ray dosages would be required and an order of magnitude increase in the complexity of the hardware. Algorithms have been developed to overcome this problem and define the edge of a structure with a greater degree of confidence. Each one has its own unique problems and for clinical use in the area of neurosurgery and otorhinolaryngology the accuracy difference is submillimetric and can be ignored.

VISUALIZATION OF IMAGE DATA

Many factors have to be considered when deciding which visualization technique to use. The clinical purpose for which the data is to be used is the most significant and the image data are rendered for that purpose. Rendering is the process of generating computer images which represent 3D anatomy with some degree of tissue transparency if that is appropriate.

Surface rendering

Optical surface scanners produce structured 3D coordinate point sets that relate to an anatomical surface.⁹ Triplets of data points are generally grouped as the vertices of adjacent triangles that interconnect to make up the entire surface. These triangular surface patches are known as facets or polygons.

The rendering of surfaces from volume data requires preprocessing. The properties of voxels containing anatomical surfaces must first be decided and voxels with these properties can then be processed. Usually the voxels are considered to lie on a surface if they are connected and all have the same associated property within a given range of values. The derived surfaces are called isosurfaces and are selected to correspond to the surfaces of anatomical structures or to surfaces of equal functional activity.

Geometric primitives are also derived from volumetric data by processes such as contour tracing, surface extraction or boundary following. Alternatively, voxels belonging to anatomical parts may be isolated from the full data set by applying thresholds to the data values associated with them. This extraction of tissue topology has become known as 'segmentation'. The derived geometric primitives (such as polygon meshes or contours) are rendered for display using conventional computer graphics techniques.

Figure 55.3b shows the rendering of a facial surface that is made up of a large set of triangular facets that are also shown in **Figure 55.3a**. This type of image can be produced using data from an optical scan of the face.

Volume rendering can be undertaken for notional surfaces between distinct tissue types. The surface normals are derived directly from the voxel values neighbouring the boundary. These derived surface normals are used for calculating the final image using algorithms. A technique of this sort was used to produce the image depicted in **Figure 55.3c**.

Volume rendering

Volume rendering has become the most commonly used method with which to visualize 3D medical image data. The basic idea is that 3D volumes are composed of voxels and that these are analogues of their 2D counterparts, the pixels. Fine details throughout a volume of interest are displayed, enabling a more direct understanding of visualized data with fewer artifacts.

This visualization technique works by projecting each voxel on to a viewing plane with a value related to the physical property represented in the voxel array. For example, a voxel containing bone with a high x-ray absorption coefficient might be projected with a high value. The most advanced systems allow the operator to construct a look-up table which relates the physical value associated with the voxel to the value it contributes to the image at the chosen viewing plane. A pixel in the viewing plane usually receives contributions from many voxels and the operator may control the manner in which these contributions are composed. For example, the operator may choose to display only the maximum contribution from any voxel along a ray. This produces an image known as the maximum intensity projection (MIP). On

the other hand, any individual voxel-associated value may be assigned a maximum opacity value to produce the same images as would be produced by surface rendering.

Figure 55.4a and **b** show two volume-rendered images with different look-up tables. These demonstrate how different anatomical structures may be made visible through others which are being rendered transparent. Major blood vessels may, for example, be effectively rendered visible within the anatomical data set.

Generally, a volume-rendered image appears different from that of a surface rendered image in that anatomical structures are presented as having some degree of transparency. For some clinical procedures, such as image-guided biopsy or transcatheter thermal ablation, transparency may greatly enhance depth perception and thus increase the accuracy of the procedure. It is apparent that surfaces are not explicitly rendered, but human perception reconstructs images that are perceived to be in the correct spatial relationship. The transparency which volume rendering offers also enables the placement of surgical instruments within 3D structures with great accuracy.¹⁰

SURGICAL PLANNING

Surgical planning is usually carried out in the surgeon's mind, drawing on past experience, knowledge of anatomy and anatomical variation. Some individuals are able to do this very well, others are not. In endoscopic sinus surgery, the surgeon must have the ability to think in 3D, having studied the information available from 2D CT slices. Surgeons may or may not be able to communicate their impressions to other surgeons. Furthermore, their mental image cannot be reviewed, audited or measured by other surgeons or indeed by the surgeon themselves when assessing patients at a later date. Planning using reconstructed 3D data enables the surgeon to assess the patient's anatomy objectively, to communicate this with other surgeons and to review these films at a later date. The data can be segmented and manipulated to familiarize the surgeon with specific features pertinent to that patient and the procedure to be performed.

SURGICAL SIMULATION

The major driving force behind the development of surgical simulators was the morbidity that accompanied the introduction of new techniques such as endoscopic 'key hole' surgery. These techniques were conceptually different from traditional surgery. Surgeons had to operate using a 2D image on a television monitor and had to develop new hand-eye coordination skills not previously required for open surgery. Training surgeons in these new skills and the assessment of their competence was entirely different from the 'apprentice-master' approach that had been the mainstay of traditional surgical teaching.

Figure 55.3 (a) Wire mesh; (b) polygon-rendered; and (c) volume surface.

Three-dimensional reconstructions of image data can be used for surgical simulation. Simulators that create a virtual surgical environment or a set of tasks that enhance hand-eye coordination skills seem to be the answer.^{11, 12}

Surgical simulators are now being developed and employed in other surgical specialties, for example skull base surgery. They are being used by trainees and experienced surgeons who might find it useful to practise a specific difficult surgical technique before performing the actual operation. Surgeons are able to 'virtually' manipulate, move and drill the mastoid process, to

perform laparoscopic or endoscopic sinus procedures. The sensations and resistance encountered during real surgery may be simulated using positive feedback mechanisms in the form of a passive robotic arm.

IMAGE-GUIDED SURGERY

A thorough knowledge of anatomy is essential for all types of surgery, particularly those using microscopes and endoscopes. Preoperative imaging alerts the surgeon to

Figure 55.4 Volume-rendered data with different look-up tables

variations of anatomy that are either inherent in the patient or caused by a disease process or previous surgery. As stated before, image guidance offers the surgeon the ability to use the patient's image data intraoperatively to determine position, distance to vital organs and other anatomical features that might be hidden from direct vision. Structures in the vicinity of the skull base are either embedded or closely adherent to bone, making this region ideal for image guidance as CT has great spatial accuracy.

Two fundamental processes are required for intra-operative image guidance, registration and tracking. Registration is the process that relates the patient in the operating theatre to preoperatively acquired image data sets. Tracking is the mechanism of following the position of the patient or an instrument within the operative field.

Both processes are potentially subject to significant mathematical error and it is vital that how this might happen is fully appreciated.

Registration

Once the patient is secured on the operating table, registration of the Cartesian coordinates of the CT scan to that patient in the theatre is achieved by one of two methods. The first is by locating anatomical landmarks visible both on the patient and image data using a probe that is visible to the tracking device. For example, using navigation software, the surgeon would point to pre-specified landmarks, such as the tragus, outer canthus and nasion. This is usually sufficient to achieve a registration accuracy or error of 3–4 mm. This can then be improved by entering a random sample of points from around the operative region (typically 40–100 points) using the probe. The position of the tip of the probe is identified by the tracking device and the coordinates are fed back to the navigation software. In this way, accuracy/errors of 2–3 mm can be achieved.

Other methods of registration use masks¹³ and laser scanning tools (Figure 55.5).¹⁴ These speed up the acquisition of surface points. With all these methods, calculations made in real time indicate the point accuracy. It is then up to the surgeon to reject or accept that point in order to improve the overall registration accuracy. Some types of IGS systems make use of fiducial markers that are applied to the patient before scanning on the day of surgery. These markers are clearly visible in both MR and CT data sets and, of course, on the patient when in theatre. They help to improve the accuracy of registration.

No matter whether skin fiducials or anatomical landmarks are used for registration, these reference points should describe or be immediately adjacent to the surgical field. Failure to pay attention to this results in navigational inaccuracies. It is important to realize that the registration error is only a measure of the accuracy of correlation between selected points in the virtual data set and the fiducial markers or anatomical landmarks identified on the patient. It is not synonymous with target error, which is the error that could be expected if a probe was placed on a random point of interest within the surgical field. The target error is influenced by the registration error and is unlikely to be much worse if the target is within the volume described by the fiducial markers. However, if the point is outside that volume, the target error will be proportionately greater.

Tracking

Sensors that provide dynamic positional information are known as 'tracking devices'. They are employed in a multitude of everyday situations that range from virtual reality games to missile guidance and electronic tagging of

© Hodder Arnold / Scott-Brown 7E

Figure 55.5 (a) A laser registration being undertaken before endoscopic sinus surgery. (b) The laser beam is shone on to the skin around the operative site. (c) A band on to which fiducial balls have been mounted is attached to the patient's head.

prisoners.¹⁵ Although these measurement acquisition systems may be similar, each has different tracking properties that are optimal for a particular application. Without some form of tracking device, it would not be possible to move the patient once they had been registered. In surgical practice, tracking systems must be

very precise, consistently accurate, fast enough to provide more than 25 readings per second, be insensitive to changes in air temperature, unaffected by metal objects and able to track two objects simultaneously.

Several tracking systems have been employed over the years. Some of the earliest devices were mechanical arms fitted with potentiometers at every joint. These were fast and accurate but were cumbersome, had a restricted range of movement and hindered the movement of the tracked object to which it had to be attached. Systems based on magnetic field distribution are effective and relatively cheap. However, their disadvantage is that tracking accuracy can be both easily and significantly affected by the presence of metal objects.

Infrared light sensors are the most commonly used image-guided surgical systems. They are referred to as either active or passive devices. Active devices sense infrared light from light-emitting diodes (LED) attached to the patient or location probe. Passive tracking devices detect infrared light reflected from metallic balls attached to the patient or probe. In the latter case, the infrared light source is situated on the sensing device itself (Figures 55.6 and 55.7). In order to detect changes in the patient's head position, haloes or arches with light-emitting diodes or reflective spheres can be fitted to a Mayfield clamp or the patient's head. Systems based on light-emitting diodes are reliable if the light path is not impeded.¹⁶ Within the operating theatre an accuracy of 2–5 mm can usually be achieved.⁴ In general, optical tracking systems are expensive. Cheaper variations do exist, but they lack high degrees of accuracy.

Inertial trackers have also been developed that are small and accurate enough for virtual reality applications. These devices generally provide one rate of change of rotational measurement only; hence, a number would be

required. They are also not accurate for slow position changes. Systems based on standard ultrasound signals have the potential to achieve much greater accuracy, but are susceptible to changes in temperature and air currents. Other drawbacks include long lag times and interference from echoes and other noises in the environment.

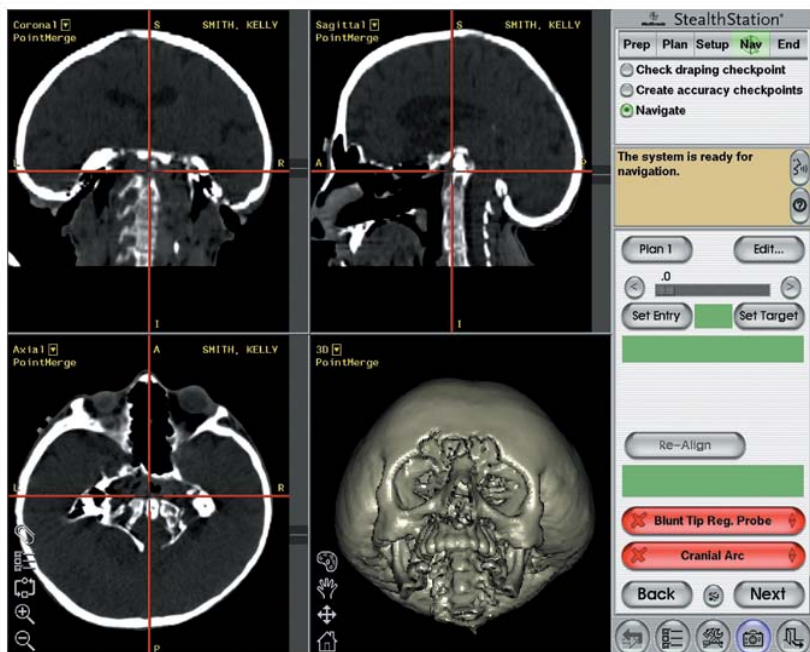

Clinical applications

Image-guided surgery offers most promise in the areas of skull base and endoscopic sinus surgery. Skull base

surgeons have found this technology particularly useful for preoperative surgical planning, design of bone flaps, identification of important structures and for finding small tumours in obscure parts. For example, in **Figure 55.8**, the guidance system had been used to maximize the access for correction of basilar invagination in a patient with osteogenesis imperfecta. The normal anatomical arrangements and landmarks were not present as a result of the disease process.

In rhinology, IGS systems are already in use in difficult revision endoscopic sinus surgery where there are no recognizable anatomical landmarks (**Figure 55.9**).¹⁷ In particular, surgeons have found the guidance systems useful to localize the frontal recess during Draf type 2 and 3 procedures, where the floor of the frontal sinus is to be opened.¹⁸ With the help of these systems, the need to perform open, external procedures will become less. Extended applications of endoscopic sinus surgery include trans-sphenoidal, trans-nasal endoscopic hypophysectomy where conventionally x-ray image intensifiers have been used to localize the sella.^{19, 20, 21}

In the field of otology, IGS has been used to aid the surgeon in locating the facial nerve, identifying and localizing lesions of the petrous apex²² and tumours, particularly in the internal auditory meatus. These include meningiomas and vestibular schwannomas.^{23, 24} It is possible that when these systems gain in acceptance, are more accurate and involve shorter set-up times, they may become mainstream intraoperative equipment in all types of mastoid surgery. Their role then would be to aid the surgeon in localizing important anatomical structures such as the facial nerve, dura, brain and jugular bulb, as well as diseases, such as cholesteatoma and acoustic schwannoma.

Figure 55.9 Functional endoscopic surgery being undertaken using image guidance.

- At present, augmented reality still has to prove its position in surgical practice. Several research groups are producing encouraging results and future reliance on these types of systems is likely to replace traditional IGS systems.
- Robots are already being used for drilling in the field of orthopaedics and to manoeuvre and control cameras in laparoscopic surgery. These are far more accurate than humans and are likely to enter other fields of surgery where there is a reliance on power instrumentation, including drills and debridors.
- In the future, we are likely to use IGS systems to audit surgical procedures as they already have the inherent capacity to store all information relating to intraoperative navigation. This will be an invaluable and, perhaps, incriminating operative record.

KEY POINTS

- IGS aids the surgeon in diagnosing the extent of disease, planning surgery and providing intraoperative positional information.
- Image-guided surgical techniques may reduce complications in endoscopic sinus surgery.
- IGS techniques offer greater accuracy and confidence in structure and disease localization.
- Major applications are skull base and revision nasal surgery where there is complex or distorted anatomy.

Deficiencies in current knowledge and the areas for future research

- Image-guided and augmented reality surgery relies heavily on technology research in the areas of computer hardware (processors, graphics and tracking) and software for segmentation and registration. Developments in these fields are driven by a variety of customer-driven demands. It is vital that clinicians make these demands and provide ideas for the computer scientists.
- The most important requirements are for accurate, robust, fail-safe systems that will give clinicians greater confidence. These systems must be user-friendly and ergonomically efficient.
- In the future, we are likely to see more developments in the areas of surgical simulation and planning. Surgical training should benefit from simulators that will enable the trainee to develop their hand-eye coordination skills prior to applying them in clinical practice.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words ultrasound or imaging and neck, head and neck neoplasm, thyroid diseases, parathyroid masses and salivary gland disorders.

INTRODUCTION

Ultrasound has achieved wide clinical use over the past half century. It is a crucial imaging modality in medical practice and now accounts for almost a quarter of all imaging studies carried out in the world. The equipment used has evolved from large expensive B-mode gantry systems with coarse, static, bistable displays, which only demonstrated organ boundaries, to convenient handheld machines with high resolution, real-time imaging with colour Doppler facility making use of digital technology. This chapter will discuss some of the basic physics and principles of both the hardware and software of the ultrasound machine and of real-time B-mode imaging. An overview of the benefits and pitfalls of the more important applications in ear, nose and throat (ENT) practice will be covered, with an emphasis on new advances and future developments.

BASIC PHYSICS AND EQUIPMENT DESIGN

Ultrasound is defined as sound with a frequency above the upper limit of normal hearing (over 20 kHz). In medical practice, much higher ultrasound frequencies are used (2.5–30 MHz) to produce an image based on the detection and display of sound waves reflected from interfaces within the body.

Ultrasound produces tomographic images similar to computed tomography (CT) and magnetic resonance imaging (MRI); however, unlike CT where x-rays are transmitted through the patient to produce an image on the other side of the patient; ultrasound images are formed from reflected sound waves. Sound waves are generated in short bursts by the transducer (or probe) and the sound energy that is reflected back is collected at the point of origin (the transducer) during the relatively long intervals between the sequential generation of sound waves. The ultrasound image is based on the back

scattering of sound energy by interfaces of tissues with different physical properties through interactions governed by acoustic physics; the amplitude of the reflected echoes is used to generate the contrast of the different tissues to form the image.

Transducer design

B-mode (brightness mode) real-time imaging is most commonly used in medical practice. The images are formed line by line from the information within the transducer that both transmits and receives ultrasound signals from the body's tissues.

A typical transducer comprises five layers (Figure 56.1):

1. a protective layer;
2. mechanical lens ('Hanafy' lens) that allows you to focus the beam in a particular elevation plane;
3. matching layers that overcome the large acoustic impedance mismatch between the ultrasound crystal and the patient's tissues (the acoustic impedance of a material is a measure of how efficiently the sound waves are conducted through the tissue);
4. an active piezoelectric material to produce the sound waves. In practice, this is usually lead zirconate titanate (PZT);
5. a backing block to stop the crystal from freely resonating and thus producing poor echoes that have inadequate axial resolution and are not useful in producing a diagnostic image.

PHYSICS OF ULTRASOUND

Sound is mechanical energy travelling through matter as a wave producing alternating areas of compression and rarefaction.¹ Sound obeys the rules of basic acoustic physics as summarized in the following equation:

$$\text{Velocity (c)} = \text{frequency (f)} \times \text{wavelength (\lambda)}$$

In the clinical setting, the ultrasound transducer generates sound waves in short bursts or pulses of energy that are transmitted into the body where they are propagated through tissues. These acoustic pressure waves may behave either as a transverse wave (travel in a direction perpendicular to the direction of the displaced particle) or as a longitudinal wave (in the same direction as the particle movement). In tissues and fluids, in medical practice, sound behaves in a longitudinal fashion.

Propagation velocity

The speed at which the pressure waves travel through different tissues varies greatly and is affected by the physical properties of the tissues, with this velocity largely

Figure 56.1 Transducer design. Schematic drawing illustrating the design of an ultrasound transducer.

dependent on the resistance of the medium to compression, as well as the tissue stiffness or elasticity. Increasing the stiffness or decreasing the density of the material will increase the propagation velocity.

In the body, the propagation velocity of sound is assumed to be constant, and is quoted at 1540 m/s. This value is the average of measurements for all the tissues and is applicable to most soft tissues of the body. However, it should be noted that some tissues, such as aerated lung and fat, have a much lower velocity than 1540 m/s, whilst others, such as bone, have a much greater velocity. In practice, this property of propagation velocity is critical as it is used to evaluate the distance of a reflecting surface from the transducer. By measuring the time it takes for an echo to return to the probe and knowing the velocity with which the wave travelled, the distance it traversed (which is the depth of the reflecting tissue interface from the probe) can be calculated.

Acoustic impedance

Ultrasound images are formed by detecting and displaying backscattered (reflected) sound waves from a reflecting surface within tissue. Sound travelling in any homogenous medium will not have such a reflecting interface and will consequently appear anechoic (black) as is seen with a simple cyst. At the junction between different tissues with different physical properties, an acoustic interface will be present. In the body, there are many of these interfaces, each of which will produce varying amounts of reflected sound that is detected by the transducer. The strength of the returning sound wave echo is determined by the difference in acoustic impedances of the materials forming the interface. The acoustic impedance is defined by the following formula:

Acoustic impedance (Z) = density (ρ) \times propagation velocity (c)

Interfaces with large differences in acoustic impedances such as soft tissue/air or soft tissue/bone, reflect almost all the incident sound waves, producing returning echoes of higher amplitude, which will form better images. In tissues where there are smaller differences in acoustic impedances, such as muscle and fat, only part of the incident sound wave is reflected and the remainder is allowed to continue on through the material; the returning sound wave echoes will be of smaller strength. It is important to note that both the propagation velocity and acoustic impedance are determined by the physical properties of the tissues and are independent of the frequency of the waves.

Image generation

The foundation of modern ultrasound imaging is with real-time, grey scale, B-mode display where the intensity/brightness of each pixel of the image represents the different amplitudes of the returning sound wave echoes. New digital technology with the consequent improvements in the software of the modern ultrasound machine has allowed improvement of image quality.

To create a two-dimensional (2D) image, multiple ultrasound pulses are sent down a series of successive scan lines, building up a 2D representation of echoes originating from the object being imaged. The image is normally displayed on a black background, with the greatest amplitude signals appearing as white and no signal as black. Signals of intermediate intensities are displayed as varying shades of grey.

In modern ultrasound machines, a digital memory of 512×512 or 512×640 pixels is used to store values corresponding to the values of the returning echoes, as well as their position in the patient. The digitally stored image can then be displayed on a video monitor by converting the digital signal to an analogue format. The dynamic range of the information stored in the digital

memory is much larger than that which can be seen on a video monitor or be appreciated by the human eye. This information needs to be compressed, a technique called 'post-processing', the purpose being to optimally view the information that is likely to be of diagnostic value and selectively eliminate less useful information stored in the memory. One important recent advance is the use of application specific integrated circuits (ASIC), which has led to improving the complexity, speed and reliability of the machines whilst reducing the cost and machine size with lower power consumption. Manufacturers have also developed new techniques to optimize the images by allowing the machine to manipulate the echo signals and therefore reducing the operator-dependent nature of ultrasound.

Real-time ultrasound gives the impression of a moving image by generating a series of 2D images at a rate of 15–60 frames per second, permitting the real-time ultrasound assessment of both anatomy and motion. This innovation has made ultrasound a dynamic examination technique.

PROGRAMME SOFTWARE TECHNOLOGY ADVANCES

Advances in digital technology² have allowed electronic and software technology improvement at all stages of the ultrasound imaging systems. Spatial compounding is an example of such a development, improving the quality of the final displayed image. With spatial compounding, the beam is electronically steered so that overlapping scans of an object are acquired at different angles. These entire scan lines are averaged to produce a real-time compound image with better spatial resolution than conventional B-mode imaging. A further example of post-processing to improve imaging is 'coded excitation'. This technique uses the fact that the transmitted pulse is digitally encoded and thus can be modified by changing its frequency or amplitude and the receiver is set to optimally receive this 'code' in the returning echoes, allowing weak signals to be distinguished from background noise. This allows imaging at higher frequency (as used in imaging the superficial structures in the neck) with improved spatial and contrast resolution at greater depth. Other recent advances, less applicable to imaging of neck structures, include 'extended field-of-view' methods that produce a panoramic image to expand diagnostic capabilities particularly in musculoskeletal ultrasound³ and tissue harmonic imaging, particularly useful in abdominal imaging.⁴

TRANSDUCER SELECTION

When choosing the optimal transducer for a given application, both the requirements for spatial resolution

and the distance of a target from the transducer need to be considered. In general, the higher the frequency of the probe, the less the depth of tissue penetration, but the better the spatial resolution. To optimize the imaging, a probe of the highest frequency is chosen that allows penetration to the depth of interest. The imaging of superficial structures requires a higher frequency probe; in the neck, most of the structures of interest are superficial and probes of greater than 7.5 MHz are used. Occasionally, in the larger individual, deeper penetration is required, usually a 5 MHz probe is used. High frequency linear array probes are ideal for imaging superficial structures as the near-field resolution is better; this allows axial resolution of 0.5 mm or less and lateral resolution of 1.0 mm or less and provide a rectangular image format that is well suited to this application.⁵ To evaluate the parotid gland area or the floor of the mouth, a curved array or sector transducer may be better suited. Curved array probes make a smaller footprint contact with the skin surface, but give a larger field-of-view at depth as it provides a sector display format.⁶

DOPPLER ULTRASOUND

Doppler ultrasound⁷ allows the imaging of blood flow in vessels; an important adjunct to grey scale imaging and has allowed greater diagnostic confidence in image interpretation. The Doppler effect is defined as a change in the apparent frequency of a wave as a result of relative movement between the observer and the source. The observer in this context is the ultrasound transducer and the source is the moving red blood cells within a vessel. The change in frequency (Doppler shift frequency) that is detected can be used to assess movement. The Doppler shift frequency is proportional to the ultrasound frequency, the velocity of the moving target and the angle of insonation of the target. These parameters are summarized in the Doppler equation:

$$\Delta f = 2 \frac{f_t V \cos \phi}{c}$$

where Δf is the Doppler shift frequency; f_t is the frequency of sound emitted from the transducer; V is the velocity of the target towards the transducer; c is the velocity of sound in the medium; and ϕ is the angle of insonation (the angle between the axis of flow and the incident ultrasound beam).

In B-mode imaging, the pulse sound wave echoes are transmitted and the backscattered signal contains information regarding phase and frequency. Precise timing allows the depth from which the echo originates to be measured. However, the additional information contained from these echoes can be used to evaluate moving targets, such as blood flow. The Doppler systems that are in use are of two kinds: continuous wave and pulsed wave Doppler systems.

Continuous-wave Doppler systems use two transducers mounted within the same housing: one transmits sound continuously and one receives the reflected echoes continuously. The traces obtained by this method can be then analysed (spectral analysis). The Doppler shift frequencies are displayed graphically and it is possible to visualize the time-varying waveform of blood flow, measure objective parameters, such as velocity, pulsatility index (PI) and resistance index (RI). The PI is the peak-to-peak value divided by the mean of the peak values throughout the cardiac cycle.

$$\text{Pulsatility index} = \frac{\text{Peak systolic velocity} - \text{End diastolic velocity}}{\text{Mean velocity}}$$

The RI is the peak systole minus the end diastole velocity divided by the peak systole velocity.

$$\text{Resistance index} = \frac{\text{Peak systolic velocity} - \text{End diastolic velocity}}{\text{Peak systolic velocity}}$$

The RI gives an indication of the degree of resistance to blood flow in the distal circulation. The disadvantage of a continuous wave Doppler system is that the range or depth of the moving structure cannot be calculated.

Pulsed-wave Doppler systems overcome this drawback by transmitting short pulses of sound waves and then leaving long intervals between to receive the returning echoes, using a single crystal. The depth of the returning Doppler signal may be calculated by timing the returning signal, with the knowledge of the speed of the sound waves in the tissues.

Duplex scanners combine colour Doppler acquisition equipment with a conventional grey-scale imaging system, allowing visualization of the vessel under interrogation and placing the sample gate over the region of interest to obtain a spectral Doppler signal. In modern machines, the switch from 2D imaging to Doppler mode is instantaneous and many machines allow continued B-mode imaging, whilst acquiring the Doppler information, a practical advantage.

MICROBUBBLE CONTRAST AGENTS

Ultrasound contrast medium⁸ is a relatively new technique and is gaining increasing acceptance in improving diagnostic accuracy. Microbubbles are less than 10 μm in diameter, cross capillary membranes and are safe, effective echo enhancers. The agent remains in the vascular compartment and is stable for several minutes after an intravenous bolus. Tissue harmonics is used to image ultrasound contrast agents by tuning the receiver to listen to a band of frequencies that allows the contrast signal to be resolved from the background, allowing visualization of vessels as small as 100 μm , enough to characterize tumour vascularity.⁹ Tumour vascularity can be further enhanced using 3D displays to demonstrate the vascular anatomy.

ADVANTAGES OF ULTRASOUND

The benefits of ultrasound imaging are well recognized. The key points to be noted are:

- Ultrasound does not use ionizing radiation making it ideal for paediatric patients, as well as for patients requiring multiple examinations, as in oncology practice.
- Ultrasound is readily available and is relatively cheap.
- Ultrasound allows good spatial resolution and is the 'gold standard' in determining whether a focal lesion is cystic or solid, surpassing even CT or MRI.
- Ultrasound is well tolerated by patients and is a 'patient friendly' technique.
- Ultrasound provides diagnostic information with a high degree of accuracy, allowing for more efficient use of CT and MRI when choosing how, if necessary, to image the patient further.
- An increasingly important role is to guide interventional procedures such as fine needle aspirations, biopsies and drainage catheter insertions accurately and in real time.

DISADVANTAGES OF ULTRASOUND

The disadvantages of ultrasound are few but are very important to consider when making clinical management decisions. The primary disadvantage is that the technique is operator dependent. There should be confidence in your operator and he/she should work in a multi-disciplinary environment to ensure the highest standards. Though the cost of this examination is relatively low, the initial capital costs need to be considered; the equipment has to be high quality. The size and position of the structures and diseases affecting the neck require high-resolution linear array and curvilinear probes with good supporting software to produce images of diagnostic quality. The facility to use colour Doppler is also highly desirable. The images obtained in ultrasound are susceptible to artifact that may cause mistaken diagnoses. The operator has to be aware how to identify, reduce or eliminate such faults from the image.

Despite these disadvantages, ultrasound is a valuable tool in the diagnosis and treatment of diseases of the head and neck and is accepted as the first imaging modality after clinical examination.

EXAMINATION TECHNIQUE

As many conditions that affect the head and neck occur bilaterally and often in an asymmetrical way, it is imperative that both sides of the neck are examined with a systematic and comprehensive approach.

It is best to examine the patient supine and to image the right side of the neck with the patient's head turned to the left and *vice versa*. The areas that should be covered are the thyroid gland, paravascular spaces, cervical triangles, supraclavicular fossae and the major salivary glands. All these areas need to be examined in at least two orthogonal planes. Colour Doppler ultrasound should also be used to assess if there is involvement of the great vessels or if there is increased vascularity in or around abnormalities.

ULTRASOUND APPEARANCES OF COMMON ABNORMALITIES

Lymph nodes

Both surgeons and oncologists use the regional classification of lymph nodes into seven levels adapted by the American Joint Committee on Cancer. Importantly, the retropharyngeal lymph nodes cannot be seen with ultrasound (Table 56.1). This group of lymph nodes is important in pharyngeal cancers and in patients who have previously undergone a neck dissection.

Ultrasound is commonly used for the evaluation of patients with enlarged cervical lymph nodes. It has been suggested that, of the numerous lymph nodes in the body, over a third are sited in the cervical region.¹⁰ Although normal lymph nodes may be visualized by ultrasound in healthy subjects, they are often not seen due to both their small size and their similar echo-texture to the surrounding structures.¹¹ When apparent, lymph nodes are invariably reactive (hyperplastic), inflammatory or neoplastic. Reactive lymph nodes are typically elongated, oval and have smooth margins, predominantly hypoechoic with an eccentric echogenic fatty hilum (Figure 56.2). The upper limit of size of a reactive lymph node in the upper jugular chain is 10 mm in the short axis.¹² However, this carries the caveat that in the paediatric population, larger hyperplastic nodes may be encountered.¹³

Table 56.1 Regional classification of lymph nodes into seven levels, adapted by the American Joint Committee on Cancer.

Level	
Level I	Submental and submandibular nodes
Level II	Upper internal jugular chain nodes
Level III	Middle internal jugular chain nodes
Level IV	Lower internal jugular chain nodes
Level V	Spinal accessory chain nodes and transverse cervical chain nodes
Level VI	Anterior cervical nodes
Level VII	Upper mediastinal nodes

See also Chapter 137, Surgical anatomy of the neck, Figure 137.5.

Figure 56.2 Reactive lymph node. (a) An oval-shaped, low-reflective lymph node with an echogenic hilum (arrow), in keeping with a reactive lymph node. (b) Florid colour Doppler flow to the central hilum consistent with a benign reactive lymph node.

Inflammatory nodes are enlarged (>10 mm), round or oval in shape with well-defined borders and in which the hilum is not readily identified. Colour Doppler ultrasound shows hilar vascularization with smooth branching of the intranodal vessels. Ultrasound may assess for the presence of an abscess formation (hypoechoic or anechoic area with no colour Doppler flow) within a mass of inflammatory nodes that may require surgical intervention.⁶ Up to 90 percent of cervical lymph node metastases are from squamous cell carcinomas (Figure 56.3) and less commonly from a primary tumour in the thyroid, breast, lung, stomach or from a melanoma.⁵ Malignant lymph nodes lose the normal ultrasound architecture, have an eccentric hilum, disordered colour Doppler signal and become more rounded (Figure 56.4).

Assessment of cervical lymph nodes, the number, level in the neck and the presence of extranodal spread are important prognostic indicators and determine therapeutic options. Most tumours from the upper gastrointestinal tract have a predictable pattern of metastases to the neck depending on the pattern of tumour extent at the primary site. It has been suggested that, if the primary tumour crosses the midline then cervical lymph nodes of both

Figure 56.3 Squamous cell carcinoma lymph node metastasis. An enlarged low reflective mass with an irregular border (long arrow), displacing the surrounding soft tissues, anterior to the carotid artery (short arrow), in keeping with a squamous cell metastasis from a primary laryngeal tumour.

Figure 56.4 Adenocarcinoma lymph node. Colour Doppler images of a low-reflective, irregular, rounded lymph node with an eccentric echogenic hilum (arrow), infiltrated by adenocarcinoma.

sides of the neck are at risk of metastases.¹⁴ [**] The reported prevalence of cervical lymphadenopathy in patients with nasopharyngeal cancer at the time of diagnosis is up to 87 percent.¹⁵ Traditionally, staging

was performed by palpation which has a sensitivity and specificity of 60–70 percent, but importantly the rate of occult metastases, undetectable with palpation, with a T1–3 oropharyngeal/supraglottic tumour is 20–50 percent.^{16,17} Ultrasound imaging has a sensitivity of 84 percent, a specificity of 68 percent and an accuracy of 76 percent in detecting abnormal nodes, improved further with the combination of ultrasound-guided fine-needle aspiration cytology (FNAC) to 97 percent sensitivity and 93 percent specificity.¹⁸ [***] The important morphological ultrasound characteristics of lymph nodes to ascertain the presence of malignant change are summarized in Table 56.2.¹⁹ [***]

LYMPH NODE SHAPE

The ‘roundness index’ (longitudinal to transverse diameter ratio) of less than 1.5 indicates metastases in 71 percent of nodes. If the ratio is greater than 2.0, then 84 percent of such nodes are inflammatory or reactive.²⁰

LYMPH NODE SIZE

Optimal size is difficult to define as the size of lymph nodes varies with the site in the neck, varying from 5 to 30 mm and the presence of micrometastases does not always cause enlargement.^{12,21} Traditionally, the maximum short axis diameter is quoted in such situations and a cut off of 10 mm is widely accepted. However, when all three lymph node diameters are assessed, the minimal axial diameter is the best criteria for enlargement.¹² The most acceptable size of minimum axial diameter is 7 mm in the upper internal jugular chain and 6 mm for the rest of the neck.²² It is important to note that the lower the limit criteria for nodal size, the higher the sensitivity in differentiating malignant from benign nodes, but this is at the cost of lower specificity. Conversely, the higher the limit criteria for nodal size, the lower the sensitivity but with increased specificity.

LYMPH NODE ECHOGENICITY

Nodes containing metastases are usually hypoechoic when compared with adjacent muscle.²³ In metastatic papillary

carcinoma of the thyroid, lymph nodes are hyperechoic (87 percent) and homogenous (81 percent). Peripheral echogenic foci are seen in 68 percent of metastatic nodes from papillary carcinoma of the thyroid and have been histologically correlated to psammoma bodies; a characteristic and important feature to recognize.²⁴ With the newer high-resolution transducers, lymphomatous nodes have a reticular echo pattern, but on the older machines these nodes had a ‘pseudocystic’ appearance of low reflectivity with posterior enhancement (Figure 56.5).²⁵

CYSTIC/NECROTIC NODES

The heterogeneous appearance of nodes with cystic spaces, representing areas of necrosis, is seen most commonly with squamous cell carcinoma, but this is a nonspecific finding seen with melanoma, papillary thyroid carcinomas and with tuberculous nodes.²⁶ Cystic necrosis appears as echo-lucent areas within the lymph nodes (Figure 56.6).

CALCIFICATION

Intranodal calcification is unusual in metastatic nodes, except in papillary cell thyroid carcinoma, where calcification is reported in 69 percent.²⁴ Calcification is also found rarely in irradiated or post-chemotherapy lymph nodes.²⁶

ECHOGENIC HILUM

The presence of an echogenic (fatty) hilum is associated with benign disease. Normal lymph nodes have an echogenic hilum in 75–100 percent, whereas it is reported that there is an absent hilum in 96 percent of metastatic lymph nodes,²⁷ 63 percent of lymphomatous lymph nodes²⁸ and 83 percent of tuberculous lymph nodes.²³

Table 56.2 Ultrasound morphology of malignant infiltrated lymph nodes.

Morphology
Round shape

Figure 56.6 Tuberculous lymph nodes. Collection of lymph nodes, with necrosis occurring (arrows) in the posterior lymph nodes, manifest as low reflective fluid. The anteriorly located lymph node has the appearance of a reactive lymph node.

However, as an echogenic hilum is found in both benign and malignant nodes, an echogenic hilum alone should not be used to assess cervical lymph nodes.²⁹

VASCULAR PATTERN

Normal and reactive lymph nodes examined with colour Doppler are either avascular or demonstrate hilar vessels with regular branching, whereas metastatic lymph nodes demonstrate tortuous vessels with an aberrant pattern, a peripheral vascular pattern or a mixture of both.³⁰ The accuracy of differentiating metastases from benign reactive lymph nodes using these criteria is 88 percent (sensitivity 89 percent, specificity 87 percent).³⁰ Tuberculous lymph nodes may have a variable vascular pattern on colour Doppler imaging and simulate both benign and malignant conditions.³¹ Vessels displaced to one side of the lymph node, a relatively common feature in tuberculous lymph nodes (81 percent), is not seen in normal lymph nodes and is uncommon in other pathologies; a useful feature in classifying such lymph nodes.³¹

Using spectral Doppler ultrasound, comparing the highest PI and RI within suspect lymph nodes, malignant nodes showed low resistance flow. Malignant lymph nodes have a PI ≥ 1.1 or an RI ≥ 0.7 , with the accuracy of differentiating malignant from benign lymph nodes estimated at 76 and 73 percent, respectively.³⁰

Ultrasound microbubble contrast medium has also been used to help evaluate the nature of cervical lymph nodes, where smaller vessels in the lymph nodes are more obvious and the typical pattern of vascular distribution can be ascertained with greater clarity.³² A high degree of accuracy (99 percent) and a change of diagnosis in 14 percent have been reported with microbubble contrast-enhanced imaging of lymph nodes, with a particularly useful role in smaller or borderline sized lymph nodes.³² [***]

Thyroid gland

The thyroid gland is a superficial structure and is favourably sited for ultrasound examination. High-frequency B-mode and colour Doppler ultrasound is widely used in both the diagnosis and follow-up of patients with thyroid diseases.

Examination technique consists of obtaining longitudinal and transverse images of the lower half of the neck from the midline. The thyroid gland is made up of two lobes connected medially by the isthmus, which has a transverse course. A third (pyramidal lobe) arises from the isthmus in 10–40 percent of normal individuals. The parenchyma has a homogenous echo texture, which is of higher reflectivity than adjacent muscle.

The thyroid gland is initially assessed for size, which varies with body habitus. Thin subjects have glands that measure 70–80 mm in length and 7–10 mm in depth. Obese patients have glands measuring less than 50 mm in length with an anteroposterior diameter of up to 20 mm.³³ Thyroid volumes have also been used to assess size and are calculated from the right anteroposterior (RAP) diameters and left anteroposterior (LAP) lobes using the following formula:

$$\text{Volume of gland} = (6.91 \times \text{RAP}) \\ + (3.05 \times \text{LAP}) - 3.48$$

Thyroid volume for males is 19.6 ± 4.7 mL and for females is 17.5 ± 3.2 mL.³⁴ Volumetric studies can be easily performed using 3D ultrasound, but unfortunately this technique is not widely available.

THYROID DISEASE

For ultrasound imaging, thyroid disorders may be broadly considered in two groups: nodular and diffuse. Almost all diffuse thyroid disease and the majority (90 percent) of thyroid nodules are benign, with thyroid malignancy a rare entity accounting for only 1 percent of all cancers.³³

THYROID NODULES

There are five major roles of ultrasound in the assessment of nodular diseases:

1. detection of focal masses;
2. differentiation of multinodular goiter/hyperplasia from other nodular diseases;
3. to document the extent of a known thyroid malignancy;
4. follow up to look for residual, recurrent or metastatic carcinoma;
5. guidance for FNAC or fine needle aspiration for biopsy (FNAB).

GOITROUS NODULES

Multinodular goiters or hyperplasia is the most common abnormality encountered (80–85 percent).³³ Hyperplasia is recognized as either a diffuse or nodular form. The nodules are separated by normal parenchyma and are mostly isoechoic or hyperechoic with well-defined margins. The adjacent great vessels may be displaced posterior or laterally, but the walls are never involved (Figure 56.7). Less than 5 percent of thyroid nodules are hypoechoic, cystic areas are seen in 60–70 percent of cases secondary to haemorrhage or collections of colloid substance.³³ Colloid substance gives a typical ‘comet tail’ artifact within the nodules.³⁵ Up to a quarter of goitrous thyroid nodules, particularly in the elderly, have areas of macrocalcification, seen as curvilinear, annular or dystrophic areas of high echoes with posterior acoustic shadowing. Colour Doppler ultrasound shows these thyroid nodules to have less vascularity than the surrounding normal parenchyma.³⁶

ADENOMATOUS AND MALIGNANT NODULES

Adenomas and thyroid carcinomas account for most of the nongoitrous nodules, with adenomas accounting for 5–10 percent of all thyroid focal lesions. Thyroid adenomas have a variable appearance on ultrasound, appearing as isoechoic, hypoechoic or hyperechoic masses.^{13, 33} Thyroid adenomas have a thick, echo-poor halo, thought to be a fibrous capsule (Figure 56.8). The blood supply is often a regular, ‘spoke-and-wheel’ type of appearance on colour Doppler ultrasound.³³

Malignant neoplasm of the thyroid are rare (two to three cases per 100,000 individuals) and may be classified

as follows:

- papillary cell carcinoma;
- follicular cell carcinoma;
- anaplastic cell carcinoma;
- medullary cell carcinoma;
- lymphoma.

Papillary cell carcinoma

Papillary carcinoma is the most common thyroid neoplasm and makes up 60–70 percent of all thyroid malignancies.³³ On ultrasound, the characteristic appearance is that of a hypoechoic, solid nodule, with up to a third demonstrating cystic changes with detectable blood supply within the intracystic septa (Figure 56.9). Punctuate areas of microcalcification are seen in 85–90 percent of lesions; a highly reliable feature in diagnosing papillary carcinoma.³⁷ Microcalcifications are only seen with the appropriate high frequency imaging, appearing as highly echogenic areas without the posterior acoustic shadowing normally seen with calcification. Colour Doppler studies demonstrate increased vascularity with a chaotic arrangement of blood vessels in 90 percent of lesions, due to arteriovenous shunting, as well as tortuous vessels within the malignant lesion.³⁸ Regional lymphadenopathy may be present at initial diagnosis in 50 percent of patients.³⁹ Recurrent lymphadenopathy may develop even after a total thyroidectomy, with the lymph nodes demonstrating microcalcification, cystic change and chaotic hypervascularity, similar in appearance to the primary tumour.³⁷ [***]

Follicular cell carcinoma

Follicular cell carcinoma accounts for 5–15 percent of all thyroid malignancies, is seen in older patients and often develops in pre-existing thyroid adenomas; approximately 60–70 percent of follicular cell carcinomas are associated with a hyperplastic or adenomatous thyroid nodule.³³ On ultrasound, follicular cell carcinomas are solid,

Figure 56.7 Multinodular goitre. A large multinodular goitre, in a transverse view, at the level of the thyroid isthmus and trachea (arrow), demonstrating two large nodules (short arrows).

Figure 56.8 Solitary thyroid adenoma. A transverse section through the thyroid gland at the level of the thyroid isthmus, with a left lobe solitary adenoma present as a well-circumscribed isoechoic lesion (arrow).

Figure 56.9 Papillary cell carcinoma. A solitary nodule (long arrows) in the right lobe of the thyroid demonstrating an irregular margin and punctate areas of calcification (short arrow).

homogenous, hyperechoic or isoechoic nodules with a thick irregular capsule and tortuous perinodular and intranodular vessels often with extracapsular spread. Unfortunately, the presence of extracapsular spread, a crucial feature, may be difficult to demonstrate, the capsular and vascular invasion only being detectable on histology.

Anaplastic carcinoma

Anaplastic carcinomas account for 5–10 percent of all thyroid cancers and, are aggressive tumours seen mostly in the elderly patient. Anaplastic carcinomas are diffusely hypoechoic with areas of necrosis in 78 percent and dense amorphous calcification in 58 percent of lesions.⁴⁰ The boundaries of the tumour nodules are irregular due to early invasion of adjacent structures, with nodal or distant metastases seen in 80 percent.³³ [***/*]

Medullary cell carcinoma

Medullary cell carcinoma, an uncommon tumour, is familial in 20 percent with an association with multiple endocrine neoplasia (MEN IIa) syndrome. In MEN IIa, the medullary cell carcinomas are often multicentric, bilateral or both (**Figure 56.10**). On ultrasound, medullary cell carcinoma is similar to papillary cell carcinoma being hypoechoic with irregular margins, demonstrating microcalcifications and irregular vascularity.⁴¹ An important distinguishing feature is the frequent presence of metastatic lymphadenopathy in medullary cell carcinoma.

Figure 56.10 Medullary cell carcinoma. Multifocal well-circumscribed, low reflective areas within the left lobe of the thyroid (arrows), with no colour Doppler signal present.

Primary thyroid lymphoma

Primary thyroid lymphoma is a rare tumour, making up 4 percent of all thyroid tumours, mostly of the non-Hodgkin's type and in 70–80 percent of cases arise from a gland with pre-existing chronic thyroiditis.³³ Primary thyroid lymphoma appears as a hypoechoic, lobulated, vascular mass lesion with large areas of cystic necrosis and encasement of nearby large neck vessels.⁴² The adjacent thyroid parenchyma is usually heterogeneous as a consequence of the underlying chronic thyroiditis. [**]

DIFFUSE THYROID DISEASE

Several pathological processes of the thyroid involve the gland in a diffuse manner: acute suppurative thyroiditis, subacute granulomatous (De Quervain's) thyroiditis, chronic lymphocytic thyroiditis (Hashimoto's disease), colloid diffuse goiter and Graves' disease. Colloid diffuse goiter and Graves' disease are the most common cause of thyrotoxicosis. Ultrasound has a limited role in the diagnosis in these disorders, as assessment is based on clinical and biochemical findings.³³

In Graves' disease, the gland is lobulated and enlarged with a reduction in size used as an indicator of therapeutic success.⁴³ The parenchyma is more homogenous than a diffuse goiter due to the presence of a large number of intraparenchymal vessels which are seen on colour Doppler ultrasound as turbulent flow within arteriovenous shunts; the 'thyroid inferno' or 'thyroid storm' (**Figure 56.11**).⁴⁴ In the normal thyroid gland, Doppler ultrasound of the intrathyroid arteries demonstrates a peak systolic velocity (PSV) of 20–40 cm/s and an end diastolic velocity (EDV) of 10–15 cm/s. However, in thyroid disease, the PSV is

© Hodder Arnold / Scott-Brown 7E

Figure 56.11 Thyrotoxicosis. (a) Transverse image through the thyroid gland demonstrating normal parenchymal reflectivity in a patient with thyrotoxicosis. (b) The florid colour Doppler signal in the thyroid gland of the same patient is demonstrated, termed a 'thyroid storm'.

elevated to 50–120 cm/s due to increased flow rates.^{33, 43} There is no correlation between gland hyperfunction and vascularity, measured flow or velocity rates.³³ [***]

In Graves' disease, hypoechoic parenchymal echotexture with a high flow rate in the thyroid arteries is suggestive of post-treatment relapse.⁴³ During the course of medical treatment, Doppler studies of the vessels demonstrate a marked fall in flow velocities measured in the superior and inferior thyroid arteries, proportional to the decrease in free circulating thyroid hormone.

Subacute (De Quervain's) thyroiditis is a clinical diagnosis, but on ultrasound the appearances may be characteristic (**Figure 56.12**).³³ Initially, the gland enlarges with ill-defined, irregular margins. Subsequently, the parenchyma becomes hypoechoic and colour Doppler ultrasound demonstrates either normal or decreased flow. As the disease progresses, the gland recovers at different rates and assumes a 'pseudonodular' configuration. Hypoechoic areas may enlarge at follow-up ultrasound, necessitating further medical treatment, where ultrasound assumes an important role.³³

Chronic autoimmune thyroiditis is visualized as an enlarged gland with lobulated margins, internal fibrous septa and micronodules. The micronodules are seen as

© Hodder Arnold / Scott-Brown 7E

Figure 56.12 Thyroiditis. (a) An enlarged thyroid gland with scattered 'pockets' of low reflectivity. (b) Colour Doppler ultrasound demonstrates a florid increase in vascularity with the inflammatory process.

hypoechoic areas measuring 1.0–6.5 mm, dispersed throughout the entire gland.⁴⁵ On histology, micronodules represent massive infiltration of plasma cells and lymphocytes. The presence of micronodules is highly suggestive of chronic autoimmune thyroiditis, with a positive predictive value estimated at 94.7 percent.⁴⁵ Colour Doppler ultrasound demonstrates increased vascularity similar to the 'thyroid inferno' described in Graves' disease, but the flow velocities are within normal limits both before and during treatment.³³ The end stage of chronic autoimmune thyroiditis is gland atrophy; ultrasounds demonstrating a small gland with ill-defined margins, a heterogeneous echo-texture and absent colour Doppler flow.³³

RELIABILITY OF ULTRASOUND EXAMINATION OF THYROID NODULES

The finding of a thyroid nodule during an ultrasound examination requires the examiner to try and determine if

sensitivity 60 -90; Specificity 60 90%

the nodule is malignant or benign.³⁶ The reliability of B-mode ultrasound imaging with colour Doppler in differentiating benign from malignant nodules based on morphological and vascular features is reported to have a sensitivity of 63–87 percent, specificity of 61–91 percent with an overall accuracy of 80–94 percent.³³ Early work with ultrasound microbubble agents has been encouraging; in carcinomas, there is a significantly reduced measured arrival time of the contrast agent in comparison to hyperplastic or adenomatous nodules, but no significant difference in arrival time of the contrast agents in benign nodules.⁴⁶ FNAC is the most accurate way of distinguishing benign from malignant thyroid nodules with a reported sensitivity of 65–98 percent, specificity of 72–100 percent, false negative rates of 1–11 percent and false positive rates of 1–8 percent.⁴⁷ [****] Ultrasound is used to guide such procedures to increase the diagnostic yield of samples.

Parathyroid glands

Normal parathyroid glands are not usually visible due to their small size and similar echo-texture to adjacent thyroid tissue. Occasionally, normal parathyroid glands are seen as either hypoechoic or hyperechoic oval areas adjacent to the lower or upper poles of the thyroid gland.⁴⁸ Consequently, the parathyroid glands are usually only imaged when a patient has biochemical evidence of hyperparathyroidism.

Primary hyperparathyroidism may be secondary to either an adenoma (where a single gland is involved), hyperplasia (where all four glands are involved) or rarely a carcinoma. Adenomas are the main cause of primary hyperparathyroidism (80 percent of cases). Secondary hyperparathyroidism is usually a consequence of chronic hypocalcaemia in patients with chronic renal impairment.

Parathyroid adenomas and hyperplastic glands are oval in shape, measuring 7–15 mm in length and are usually hypoechoic in comparison to adjacent thyroid tissue (Figure 56.13).⁴⁹ Parathyroid adenomas have an echogenic capsule and are usually vascular on colour Doppler ultrasound with prominent diastolic flow demonstrated on spectral Doppler ultrasound. Areas of calcification are rare in parathyroid adenomas, but more common in hyperplasia and carcinoma.⁴⁹

Intrathyroidal parathyroid glands are seen in 1 percent of cases and mimic thyroid nodules as they appear as hypoechoic areas with well-defined margins.³³ Solitary parathyroid cysts are rare, often occurring below the level of the inferior thyroid margin. The cystic fluid in functioning lesions contains high levels of parathyroid hormone.⁵⁰

The sensitivity of ultrasound in localizing parathyroid glands in primary hyperparathyroidism is between 70 and 82 percent.^{51, 52} However, in persistent or recurrent hyperparathyroidism, the sensitivity falls and ranges from 36 to 63 percent.⁵³

Salivary gland disease

Both the parotid and submandibular glands are superficial and well sited for ultrasound examination. The parotid glands are examined, initially in the axial plane in order to identify anatomical landmarks before completing the examination in the coronal plane. The submandibular glands are best seen in the coronal plane with paramandibular images as useful adjuncts. The normal submandibular gland parenchymal echo-texture is of a homogenous, highly reflective nature, well demarcated from surrounding tissues. The parotid gland is generally

of higher echogenicity than the submandibular gland. The parotid (Stensen's) and submandibular (Wharton's) ducts are only seen on ultrasound when dilated.⁶

SALIVARY GLAND TUMOURS

Salivary gland tumours account for 3 percent of all head and neck tumours.^{54, 55} Ultrasound accurately differentiates salivary gland tumours from other lesions outside the gland in 98 percent of cases.^{54, 56} Tumours that arise in the parotid gland are benign pleomorphic adenomas in 80 percent of cases. The accepted treatment for pleomorphic adenomas is parotidectomy, as there is a 40–50 percent recurrence rate if they are only enucleated.^{54, 57} Malignant transformation is reported in 3–10 percent of cases, with the risk increasing with time.⁵⁵ Pleomorphic adenomas are typically hypoechoic, slightly heterogeneous solid mass lesions with a smooth lobulated outline (Figure 56.14). Unusually, unlike other soft tissue masses, pleomorphic adenomas exhibit through transmission of sound in a similar fashion to simple cysts.⁵⁶ Ultrasound delineates pleomorphic adenomas in the parotid in 95 percent of cases and further cross-sectional imaging is advised in only in a minority of cases.⁵⁵ [**/*]

The second most common tumour in the parotid gland is a Warthin's tumour (adenolymphoma), accounting for 2–24 percent of parotid tumours.⁵⁴ Adenolymphomas are markedly hypoechoic due to the increased mucus content of cysts and contain discrete septations, suggested as characteristic of adenolymphomas.^{55, 58} Parotid carcinomas are rare and are hypoechoic, heterogeneous lesions with irregular margins.⁶ When differentiating malignancy from benign lesions using irregular margins as a marker for malignancy, ultrasound has an accuracy of 94 percent in lesions over 1.0 cm. However, using this as the only criterion is limited, as up to 28 percent of malignant tumours have well-demarcated borders.⁵⁶ [*]

SIALOLITHIASIS

The majority of salivary gland calculi (80 percent) occur in the submandibular gland.⁵⁶ Calculi larger than 2 mm may be detected on ultrasound, with a typical appearance of an echogenic rim with posterior acoustic shadowing (Figure 56.15). Calculi impacted at the ostium are not well seen on ultrasound, but often main salivary duct dilatation as well as intraglandular duct dilatation are present, with gland enlargement and a heterogeneous, hypoechoic appearance (Figure 56.16).⁵⁹ Both intra- and extraductal calculi may be treated with ultrasound lithotripsy but symptomatic intraparenchymal calculi require surgical removal. Ultrasound is useful in defining the location of calculi in relation to the gland parenchyma, which has important implications for clinical management.⁵⁵ [*]

Figure 56.16 Submandibular gland duct dilatation. Dilated main duct in the submandibular gland.

INFLAMMATORY AND AUTOIMMUNE DISORDERS

Acute inflammation causes swollen salivary glands and this enlargement may be documented on ultrasound and compared to the contralateral side if unaffected, or to established normal measurements. Inflammation causes the gland to appear heterogeneous and hypoechoic on ultrasound; the main role of ultrasound is to exclude salivary duct dilatation.⁵⁶ Ultrasound may also identify any complications, such as abscess formation, and image guidance could then be used to aspirate fluid for microbiological analysis.

Acute suppurative sialadenitis is a painful condition occurring in postoperative, dehydrated and debilitated patients, seen almost exclusively in the parotid gland. Ultrasound may demonstrate an enlarged, well-defined gland with either a hypoechoic or hyperechoic parenchymal echo-texture. The role of ultrasound in this situation is to detect the presence and extent of any abscess formation.⁵⁹

In chronic inflammation, one or both parotid glands appear heterogeneous with a small number of hypoechoic lesions, measuring up to 10 mm in diameter, often with associated reactive lymph nodes with their characteristic echogenic hilum present.⁵⁶ In Sjögren's syndrome, there is bilateral gland enlargement, which on ultrasound may appear of normal or hyperechoic texture with enlargement in the early stages.⁵⁹ As the disease progresses, the gland becomes atrophic with multicystic changes and a reticular pattern. The degree of parenchymal damage correlates well with glandular vascularity on colour Doppler ultrasound imaging.⁵⁹ As there is an increased risk of developing lymphoma, ultrasound may be used in the follow up of these patients.⁶⁰ [**]

CYSTIC LESIONS

Soft tissue cystic lesions occur with a frequency of 1–10 percent in the neck, with ultrasound able to clearly

differentiate solid from cystic abnormalities.⁶¹ Necrotic lymph node metastases from squamous cell carcinoma of the head and neck or papillary carcinoma of the thyroid may appear cystic and caution is needed in interpretation. Any lymph node is likely to demonstrate increased vascular flow with colour Doppler ultrasound, which may be used as a discriminator.⁵ [*]

Thyroglossal cysts

Thyroglossal cysts occur close to the midline over the anterior aspect of the neck, anywhere between the foramen caecum to the pyramidal lobe of the thyroid gland. Thyroglossal cysts appear as anechoic areas with posterior acoustic enhancement, with the typical appearance of a cyst (Figure 56.17).^{62, 63} The majority of thyroglossal cysts occur in the region of the hyoid bone and tend to communicate with the bone. This latter finding should be specifically sought on ultrasound, as this will allow the corpus of the hyoid bone to be removed with the cyst at the time of surgery.⁵⁶ It is possible on ultrasound imaging to establish if the cyst is multilocular or if a fistula is present.⁶²

Branchial cysts

Branchial cysts most commonly arise from the first or second branchial clefts and are found in the region of the parotid glands or anterolateral to the carotid bifurcation. Branchial cysts vary in appearance on ultrasound from anechoic to heterogeneous, depending on the amount of cellular debris or cholesterol crystals in the cysts (Figure 56.18).⁶⁴ There is no vascularity on colour Doppler ultrasound and if there is colour Doppler signal, the possibility of a branchiogenic carcinoma should be raised.⁶

Dysontogenetic cysts

Epidermoid, dermoid cysts and teratomas are included in the dysontogenetic cyst group, occurring in the midline from the floor of the mouth or tongue.⁶⁵ These lesions are usually hypoechoic, but may have high reflective echoes due to the presence of hair, sebum and fluid.⁶⁶ The presence of calcification is considered characteristic of teratomas.⁶

Laryngoceles

Laryngoceles are dilatations of the saccule of Morgagni containing mucus, saliva and air, and are classified relative to their position to the larynx. Laryngoceles are seen as anechoic lesions if examined thorough an uncalcified thyroid cartilage.⁶⁷

Figure 56.17 Thyroglossal cyst. A thick-walled, bilobulated thyroglossal cyst is present in the soft tissues above the hyoid bone (long arrows). Echogenic debris, manifest as reflective areas, is present within the cyst, which demonstrates characteristic posterior acoustic enhancement (short arrow).

Figure 56.18 Branchial cyst. A cystic abnormality present in the soft tissues of the lateral aspect of the neck, with an area (arrow) of echogenic debris present.

Ranulas

Ranulas are mucous retention cysts of the minor sublingual salivary glands and can extend over the posterolateral aspect of the mylohyoid muscle. Ranulas are recognized as hypoechoic lesions with smooth, well-defined margins with no colour Doppler signal.⁶

SOFT TISSUE NEOPLASMS

Ultrasound is often the only technique used for imaging non-nodal cervical lesions. CT and MRI are used as adjuncts in patients where the lesion is not completely delineated or a specific diagnosis is not made by ultrasound. [*]

Lipomas

Lipomas are common soft tissue masses that are oval, elongated lesions with varying echogenicity depending on the amount of fat and fibrous tissue within the lesion (**Figure 56.19**).⁶⁸ The greater the fat content, the more hypoechoic the lesion appears, with the echogenic manifestation due to the presence of multiple fat–water interfaces within the lesion acting as reflectors, thus

Figure 56.19 Lipoma. A well-circumscribed isoechoic abnormality (arrows) in the soft tissues of the neck causing displacement of the surrounding tissue planes with no increase in colour Doppler signal.

increasing the number and intensity of reflected echoes.⁶⁹ In the rare cases where there is doubt, CT or MRI can confirm the presence of fat.

Paragangliomas

Paragangliomas are tumours arising from the autonomic nervous tissue, commonly the carotid body or vagal ganglia (**Figure 56.20**). Paragangliomas appear as hypoechoic solid tumours and lie between the bifurcation

Figure 56.20 Carotid body tumour. A low reflective abnormality (between arrows) with evidence of displacement of the internal carotid artery (ICA) and the external carotid artery (ECA).

of the internal and external carotid arteries. Colour Doppler ultrasound demonstrates a markedly vascular lesion with a low resistance flow, resultant to arteriovenous shunts.⁷⁰ Ultrasound is additionally useful in the follow up of these patients to facilitate early detection of recurrence.⁶

Neurogenic tumours

Neurofibromas and schwannomas, when they are present in the neck, are most commonly sited in the posterior triangle. Neurogenic tumours are well-defined, hypoechoic, fusiform lesions with a number of central cystic areas in continuity with a nerve and exhibit posterior acoustic enhancement.⁷¹ With neurofibromas, the nerve enters the centre of the lesion, whereas in schwannomas the mass is eccentric to the nerve and this may be demonstrated on ultrasound. Schwannomas have a variable vascularity but are generally hypervascular, whereas neurofibromas are less vascular which may be an important distinguishing factor between these two entities.⁷¹

Vascular malformations

Haemangiomas are the most common tumour in infants and up to 60 percent will occur in the head and neck area.¹³ Vascular-based lesions may be seen in the prenatal period, are usually evident in the first two years of life and are classified into two broad categories: haemangiomas and other vascular malformations. Vascular malformations

are further divided depending on flow characteristics and the presence of anomalous channels.⁷² It is important to distinguish between haemangiomas and other vascular malformations as they are treated differentially and have different outcomes. A haemangioma does not regress spontaneously. Haemangiomas are a clinical diagnosis and the role of imaging is to identify deep malformations or if they present as an atypical soft tissue mass. Haemangiomas have a variable ultrasound appearance depending on the number of 'cystic' vascular spaces present. Small lesions are usually echogenic but often the larger lesions are hypoechoic, compressible with increased colour Doppler flow.⁷³ Lesions in the proliferative phases have increased colour Doppler flow with increased vessel density (>5 vessels/cm²) and a low resistance pattern on spectral Doppler ultrasound.^{72, 74}

Congenital venous malformations occur in the head and neck in 40 percent of cases, but are often not diagnosed at birth.^{13, 72} Grey-scale imaging can aid the diagnosis of a venous malformation. The majority of venous malformations are heterogeneous and hypoechoic relative to the subcutaneous tissue and phleboliths are seen in 16 percent.⁷³ On spectral Doppler ultrasound, venous malformations tend to have a low velocity monophasic flow pattern and mixed vascular lesions tend to have a low velocity, biphasic flow pattern.⁷³ If the flow velocity is so low to be below the level that can be detected with normal colour Doppler imaging, then the administration of ultrasound microbubble contrast agent may help.¹³ Arteriovenous malformations (AVM) have a heterogeneous appearance due to visualization of the feeding vessels; colour and spectral Doppler analysis show high vessel density with high systolic flow from numerous sites of arteriovenous shunting. Distinct from haemangiomas, an AVM always demonstrates pulsatile flow in the veins caused by arterIALIZATION of the veins.⁷²

Lymphangiomas

Lymphangiomas are thought to originate from sequestered lymphatic sacs that do not communicate with peripheral draining channels. Cystic hygromas, usually diagnosed on antenatal ultrasound examination, are a form of lymphangioma. Seventy-five percent of all lymphangiomas are located in the neck, usually in the posterior triangle, with up to 10 percent extending down to the mediastinum.⁷⁵ Four types are classified on histological criteria: cystic hygroma, cavernous lymphangiomas, capillary lymphangiomas and vasculolymphatic malformations. These four types cannot be differentiated by ultrasound as all are multilocular, predominantly cystic masses with both septa and solid components. Ultrasound may also be used to guide therapeutic sclerosing injection in the management of macrocystic lymphangiomas.⁷⁶

Ectopic thymic tissue

Ectopic thymic tissue is seen in the neck in 21–42 percent of infants and resembles a lymphoma, appearing as an echogenic mass with septa that are isoechoic with normal thymus tissue. Increased vascularity on colour Doppler ultrasound allows differentiation of ectopic thymic tissue from a lipoma.⁵

Foreign bodies

Ultrasound is useful in localizing nonradio-opaque foreign bodies, especially in the neck to guide the operator to a suture granuloma with its typical appearance of a hypo-echoic lesion with a central curvilinear echogenic line.⁶

CONCLUSION

Ultrasound is a safe, widely available imaging technique that is patient-friendly and extensively used in most aspects of clinical medicine. In neck imaging, ultrasound use has become more prevalent with the development of real-time, high frequency ultrasound transducers, digital imaging technology coupled with the inherent anatomical advantage of the superficial structures of the head and neck. Ultrasound is currently the imaging modality of choice after clinical examination in ENT practice. Ongoing improvements to ultrasound technology will lead to increased diagnostic accuracy.

KEY POINTS

- High frequency, high resolution ultrasound provides excellent visualization of structures of the neck, allowing guided interventional procedures.
- Ultrasound readily identifies enlarged lymph nodes and may usefully divide the appearances into benign or malignant.
- Ultrasound detects nodular thyroid disease, but is nonspecific in establishing the type of nodule.
- Ultrasound often identifies papillary carcinoma of the thyroid.
- Ultrasound is not sensitive, but specific for the detection of parathyroid adenomas.
- Ultrasound is a reliable method of examination for salivary gland disease.
- Ultrasound should always be the first-line imaging modality in assessing disease of the soft tissues and glandular structures of the neck.

Best clinical practice

- ✓ A linear high frequency transducer will allow the optimal resolution of the structures of the neck and will guide needle placement in the lesion for tissue sampling.
- ✓ Ultrasound of lymph nodes using B-mode, colour and spectral Doppler ultrasound allows accurate delineation of lymph nodes into benign and malignant types, but fine needle aspiration is always required.
- ✓ Ultrasound in the delineation of thyroid nodules is not specific except in papillary cell carcinoma where some ultrasound features are characteristic.
- ✓ Ultrasound defines an enlarged thyroid and, with the addition of colour Doppler ultrasound, identifies the appearances of thyroiditis and Graves' disease.
- ✓ Parathyroid adenomas have a characteristic low-reflective ovoid appearance on ultrasound, with colour Doppler flow present in the lesion.
- ✓ Ultrasound of obstructive salivary gland disease is accurate and will often identify the calculus.

Deficiencies in current knowledge and areas for future research

- Ultrasound probe technology and image post-processing will continue to improve, which will allow better visualization of neck structures in difficult patients.
- The use of microbubble contrast agents will allow physiological aspects of tumour circulation to be better understood and aid tissue characterization, using transit time and blood vessel distribution.
- Better needle visualization will allow better needle guidance for cytological analysis.
- An improvement in the identification of benign versus malignant thyroid nodules is desirable.

SEARCH STRATEGY AND EVIDENCE-BASE

The data in this chapter are supported by a Medline search using the key words interventional neuroradiology, endovascular therapy, embolization, meningioma, paraganglioma, epistaxis and tumour embolization.

The evidence base for most INR treatments is lacking. Research has largely involved reports of single institute case audits. Large-scale trials are difficult because relatively small patient numbers are treated at each hospital and multicentre cooperation is needed. This problem is currently being addressed by various specialist interest groups who have organized case registries and a large multicentre trial to study the efficacy of embolization alone for treatment of meningioma is ongoing.

INTRODUCTION

What is interventional neuroradiology and what is its role in the management of patients with pathologies of the head and neck? This chapter is intended to answer these two questions by describing the current (and future) capabilities of the discipline. Interventional radiology originated in surgery, but its complete dependence on accurate *in vivo* corporal imaging places it in radiology. In 1930, Brooks¹ closed an arteriovenous fistula of the cavernous carotid by introducing a muscle embolus via an arteriotomy in the proximal carotid artery. This desperate operation was performed in order to avoid the extensive dissection required to expose and directly repair the fistula. The need of imaging to monitor such embolization was obvious, but the capacity to do so developed slowly after the first description of cerebral angiography by Egas Moniz in 1927,² and the technologies needed to navigate catheters through blood vessels and to deposit

emboli at specific sites did not become available for another 30 years. In 1964, Lusenhop and Valasquez³ described an operation to embolize a carotidocavernous fistula using an endovascular catheter under x-ray control and the current form of most procedures was born. Interventions for head and neck pathologies are usually practised within the subspecialty of neuroradiology or, more specifically, interventional neuroradiology (INR).

The term 'most procedures' is used because endovascular embolization is the most common technique. It is used to treat arteriovenous shunts, devascularize tumours and close large arteries prior to surgical resections. However, also included in the INR repertoire are percutaneous techniques for embolization of vascular malformations and tumours, as well as image-guided biopsy and the focussed endovascular delivery of chemotherapy agents. The technologically-driven evolution of the discipline will almost certainly produce new techniques and applications to replace more invasive

surgery in the future and it remains to be seen, into which other branch(es) of medicine (or rather surgery) it extends.

INDICATIONS

Detection of head and neck lesions is by magnetic resonance (MR) or computed tomography (CT) scanning and the possible role of INR should be considered before invasive diagnostic x-ray angiography is performed. Combining embolization or functional testing with diagnostic x-ray angiography means that the indications for INR techniques should be considered early in treatment planning.

Preoperative treatment planning of patients with tumours generally involves obtaining biopsy tissue and mapping the lesion's blood supply, as well as its extent and relationship to adjacent normal structures. Information about invasion of large arteries and veins may be vital. Major vessels are at risk, either because of tumour spread or because their sacrifice is a necessary component of the surgical approach. In these situations, preoperative testing of blood supply by temporary vessel occlusion is indicated and endovascular ligation may be appropriate (see Coils and balloons).

Embolization of highly vascular tumours is indicated prior to surgical resection of these tumours in order to reduce intraoperative blood loss and operation times. It may also be indicated to relieve patients of symptoms by inducing tumour shrinkage. Embolization is targeted to occlude the tumour vascular bed, rather than feeding arteries, since occlusion of proximal arteries may fail to reduce blood supply because blood flow from collateral arteries can still be recruited. It is, therefore, most effective in tumours with a rich vascular bed. In most instances, this can be inferred from the degree of contrast enhancement evident on CT or MR scanning, but the uptake of radiographic contrast within a tissue reflects the degree of extravascular leakage of these agents and does not necessarily imply high vascularity, so occasionally tumours showing pronounced enhancement are not suitable for embolization.

The decision to perform embolization therefore depends on clinical and anatomical factors. These should be reviewed in consultation between otolaryngologist and

interventional neuroradiologist. The principle guiding the decision to recommend preoperative embolization is that the addition of the INR procedure to the patient's treatment plan should not add to its overall risk. The risk/benefit analysis may require information that can only be obtained at the time of x-ray angiography. For example, embolization via arteries with intracranial territories of supply is obviously more likely to be complicated by stroke than treatments performed entirely in extracranial vessels. Therefore, a team approach is needed to ensure that the risks of complications caused by embolization or preoperative functional testing are acceptable and are likely to improve the results of subsequent surgery. These issues, as they apply to specific tumour types, and the use of embolization in the management of epistaxis, will be discussed below. The purpose and indications for INR techniques are summarized in Table 57.1.

TOOLS USED IN INTERVENTIONAL NEURORADIOLOGY TECHNIQUES

Endovascular catheters

Transarterial or transvenous catheterizations are performed for embolization, temporary vessel closures for dynamic testing or intraarterial drug delivery. The catheters used are available in a range of sizes with shaped tips. They are used to select and inject radiographic contrast media in cranial vessels for angiography or as guiding catheters for smaller catheters used for the section of small vessels (i.e. microcatheters). Microcatheters are generally 0.02 inches (0.508 mm) or smaller in diameter and used to inject embolization materials. They are constructed with flexible distal ends for navigation through tortuous vessels and stiffer proximal sections to allow the operator to advance them by pushing.

Two basic types of microcatheters are used: flow-directed and over-the-wire catheters. The former have extremely light and supple distal ends so that they are carried by antegrade blood flow to the target position. The latter are pushed over a guide wire to the objective. Flow-directed catheters work best when blood flow is increased and are therefore used to treat arteriovenous shunts. Their size limits their use to the injection of

Table 57.1 Indications for INR techniques.

Procedure	Technique	Purpose/Benefit
Biopsy	Percutaneous needle	Appropriate treatment selection
Functional testing	Balloon occlusion	Assessment of collateral blood supply prior to surgical or endovascular ligations
Embolization of small vessels	Particles or liquid embolics	Devascularization of tumour to stop haemorrhage
Embolization of large vessels	Balloon or coils	To aid surgical exposure/dissection
Chemotherapy	Supers elective injection	To maximize drug delivery

liquids or very small particles. Over-the-wire catheters are used when blood flow is slower. The combination of guide wire and a stiffer catheter makes navigation easier and their larger lumen allows the delivery of both particles and coils. They are usually used in the treatment of head and neck tumours.

Materials used for embolization

PARTICLES

Embolic agents can be categorized on various criteria. Traditionally, they are divided according to whether the resulting devascularization is permanent or temporary. Temporary agents being autologous blood clot, gelfoam powder and microfibrillar collagen, whilst polyvinyl alcohol particles (PVA) are considered permanent agents (see Table 57.2). However, embolization using PVA is liable to be temporary because, though the particles are not degraded, their effect may be circumvented by development of new collateral vessels.^{4,5} In practice, the development of new vessels is less likely if particles can be deposited in vessels within the tumour, rather than in proximal arteries. To ensure the deep penetration of injected particles, they are engineered to mix well with radiographic contrast so that they can be injected as an even suspension. PVA or Trisacryl gelatin microspheres are currently used in the author's department. These come in a range of sizes varying between 40 and 800 microns in diameter. The choice of particle size is important because, though smaller particles will penetrate to smaller vessels, they are more likely to pass through arteriovenous shunts and reach the lungs. They are also more likely to cause ischaemic damage to normal tissues. On the other hand, larger particles occlude

Table 57.2 Embolic agents.

Agent	Embolization	Target vessels
Autologous blood clot	Temporary	Large arteries
Gelfoam	Temporary	Large arteries
Polyvinyl alcohol particles	Permanent	Tumour vessels
Trisacryl gelatin particles	Permanent	Tumour vessels
Coils	Permanent	Large arteries/veins
Balloons	Permanent	Large arteries
Alcohol (ethanol)	Permanent	Malformations or tumour vessels
Sodium tetradecyl sulphate	Permanent	Malformations or tumour vessels
Cyanoacrylate adhesives	Permanent	Malformations or tumour vessels
Ethylene vinyl alcohol copolymer	Permanent	Malformations or tumour vessels

proximal arteries and achieve less reliable tumour devascularization.⁶

The effect of PVA or gelatin particles on tissues is to cause an initial acute inflammatory response, which is followed by a chronic foreign body reaction within weeks.^{5,7} Devascularization causes ischaemia and necrosis within hours, which in turn causes tumours to swell and may exacerbate symptoms, particularly pain. Preoperative embolization is therefore best performed the day before or immediately prior to operation.

COILS AND BALLOONS

Coils are made from steel, tungsten or platinum. Because of problems of corrosion, tungsten is generally no longer used and platinum, though expensive, is preferred because it is inert and not liable to magnetization effects during MRI. A new development is to enhance their effect by adding a thrombogenic coating. The materials used to coat coils include collagen, bioabsorbable polymers and dacron fibres.⁸

Balloons are made of latex or silicone. They are either fixed to a catheter tip for temporary test occlusions or can be detached for vessel occlusion. They are inflated by injecting fluid; usually radiographic contrast media. Coils and balloons are used to occlude large vessels. The delivery of coils is easier to control than balloons and they can be positioned very accurately. There are various methods for controlling the detachment of coils from a delivery wire. These include couplings released by mechanical or hydrostatic pressure, electrolysis or thermal heating.⁹ Detachable balloons are released mechanically from a delivery microcatheter, but their detachment is less reliable than the newer methods developed for coils. In many centres they have been superseded by coils.

Coils or balloons are used for large artery occlusion (i.e. endovascular ligations) after a satisfactory temporary balloon occlusion test. High blood flow fistulas are occluded with coils or balloons positioned at the point of transition between artery and vein. Coils are also commonly used to embolize large veins or dural sinuses in order to close dural arteriovenous malformations (AVM). They are less often used in tumour embolizations.

LIQUID EMBOLIC AGENTS

Various liquids are used for embolization including sclerosants, adhesives and soluble plastics. They have the advantage over coils and particles of being injectable via small lumen catheters or needles. Most commonly used are quick-setting adhesives and polymers. The latter are used for percutaneous puncture of small vessels within tumours or facial vascular malformations. Examples of liquid agents are the tissue adhesive n-butyl-2-cyanoacrylate (NBCA) and the copolymer ethylene vinyl alcohol. There are various commercial formulations

available. NBCA thickens and sets on exposure to blood and copolymers set after injection because of solvent dispersal. Both agents are liable to stick the delivery catheter to vessels and require considerable expertise to deliver safely, but they are generally regarded as producing the most permanent form of embolization. They are therefore used for definitive or palliative treatments and in situations where immediate surgical resection is not planned. Sclerosants, such as absolute alcohol, are used to treat facial vascular malformations, but replacement agents are being tested because of toxicity problems.

APPLICATION OF EMBOLIZATION TECHNIQUES

Tumour embolization

TRANSARTERIAL

Embolization of tumours of the head and neck is most often performed to reduce blood loss and facilitate surgical resection or for palliation (Table 57.3). It is rarely curative. Preoperative embolization is performed for vascular tumours such as meningioma,^{7,9,10} haeman-gioblastoma, juvenile nasopharyngeal angiofibroma,¹¹ schwannoma and paraganglioma.¹² Functional evalua-tions by temporary balloon occlusion of major arteries at risk during surgery can also be performed. Preoperative embolization is largely reserved for extraaxial intracranial tumours and only rarely are intraaxial central nervous system (CNS) tumours treated.

Preoperative transarterial embolization is usually performed with PVA particles, sized to occlude the pathological circulation. Liquid agents, including alcohol, can be delivered transarterially by catheter, but are more frequently injected percutaneously (see below). Serious procedural complications occur in about 4 percent of patients and these include cranial nerve palsies (including blindness), stroke due to unrecognized spread of emboli and induced bleeding due to vessel perforation or tissue necrosis (see Embolization for epistaxis). Complicating cranial nerve palsies are more common when very small

particles or NBCA are used.¹³ Though technically relatively straightforward, safe embolization of skull base lesions should only be undertaken after adequate training. Safe embolization demands a sound knowledge of vascular anatomy and the potential sites of spontaneous external to internal carotid artery or vertebral artery anastomoses, if unintended cerebral or spinal migration of emboli is to be avoided.¹⁴

PERCUTANEOUS EMBOLIZATION

This technique involves the injection of a liquid embolic agent or sclerosant directly into tumour vessels (Figure 57.1). The objective is to devascularize tumours before surgical resection or for palliation of symptoms by

Table 57.3 Head, neck and skull base tumours treated by embolization.

Commonly treated tumours	Less frequently treated tumours
Meningioma	Schwannoma
Paraganglioma	Carcinoid
Juvenile angiofibroma	Alveolar sarcoma
Haemangiopericytoma	Thyroid carcinoma
	Granular cell myoblastoma
	Capillary haemangioma
	Esthesioneuroblastoma
	Neurinoma

Figure 57.1 Percutaneous embolization of facial venous angioma. (a) A coronal T1W MRI showing the left-sided lesion just below the ramus of the mandible (arrows). In (b), a lateral plain radiograph, a needle has been inserted into the angioma and radiographic contrast injected prior to embolization using ethanol. Because the venous space empties slowly, a sclerosant can be used to obliterate the lesion.

causing tumour involution. Preoperative embolization is usually performed following percutaneous puncture, but perioperative needling can be performed. The technique was first used to devascularize hypervascular juvenile angiofibromas,¹⁵ but has also been used to treat haemangiopericytoma and paraganglioma.¹⁶ The technique is particularly attractive for the management of recurrent lesions and has been reported to achieve total or near-total tumour devascularization.¹⁷

INTRAAARTERIAL CHEMOTHERAPY

Delivery of drugs via selective catheterization of a feeding artery aims to maximize the dose the tumour receives by allowing otherwise systemically toxic dose levels to be administered. The amount of drug delivered to a tumour is proportional to its rate of plasma clearance within the tissue and inversely related to tumour plasma flow.¹⁸ Selective catheterization allows the delivery rate to be fine tuned to the prevailing rate of blood flow. This benefit has been used in various studies of local chemotherapy for head and neck cancers, specifically advanced squamous cell carcinomas.¹⁹ Combination therapies with radiotherapy, for example, RADPLAT, have been effective at inducing remission, and Kumar and Robbins²⁰ recently reviewed their use. The systemic toxic effects of cisplatin can be mitigated by the simultaneous intravenous administration of its competitive antagonist thiosulphate. Despite logistical problems associated with catheterization and long infusion times, preliminary trials have shown the technique to be highly effective at causing tumour shrinkage.²¹

Temporary and permanent large artery occlusions

Temporary endovascular occlusion of large arteries prior to head and neck surgery allows angiographic and neurological testing of the awake patient to determine the consequences of vessel sacrifice. Rarely is large vessel sacrifice indicated for cancer palliation since the proximal occlusion of arteries is a relatively ineffective method of causing tumour necrosis and/or regression. Large vessel occlusions may be required to manage tumour haemorrhage, as described under Embolization for epistaxis.

There are many described protocols for temporary artery occlusion and dynamic testing. Only two elements are common to all: (1) the procedure is performed under local anaesthesia so that the patient is accessible for neurological examination and (2) anticoagulants are given. Test occlusion involves inflating a balloon in the target artery for 20–30 minutes and assessing the effect on cerebral blood flow. The adequacy of collateral blood flow to the territory of the occluded vessel can be demonstrated by angiography, Doppler ultrasound, xenon CT, SPECT and PET scanning. Additional provocative testing

can be performed by simultaneously lowering the systemic blood pressure or administering a vasodilator drug, such as acetazolamide.²² All these techniques are designed to improve the reliability of the test but the lack of a consensus protocol testifies to the fact that there remains a risk of the collateral blood flow being inadequate, despite a normal test.

It is generally accepted that preliminary testing reduces the risk of delayed stroke, but the data supporting this conclusion come largely from reports of its use in aneurysm patients.²³ Amongst patients undergoing ligation for skull base tumours, rates for complications range between 5 and 20 percent.²⁴ The additional risks faced by cancer patients were documented in a single institution report which found their complication rate to be 10 percent, whilst that of aneurysm patients was only 3 percent.²⁵ Following a satisfactory period of temporary occlusion, the artery is permanently occluded by detaching the balloon used to perform temporary occlusion, or replacing it with embolization coils. Some practitioners prefer the latter because the detachment systems for coils are more reliable. It is obviously important that permanent occlusion is performed at the same arterial level (i.e. at the same place) as the test occlusion.

EMBOLIZATION FOR MENINGIOMAS AND PARAGANGLIOMAS

Two commonly treated tumour types will be described in detail to illustrate the goals of INR in the management of patients with tumour of the skull base and neck.

Meningioma

These typically benign tumours originate from arachnoid cap cells found in arachnoid granulations. They therefore arise in continuity with dura. Though generally intracranial, they are found at extracranial sites by extension from a dural origin or rarely occur entirely extracranially (presumably from ectopic dural rests). Thus tumours may involve the skull base, orbit and cervical spine or the upper neck. They occur in middle age, affect women twice as commonly as men and are linked to a genetic deficit on chromosome 22. Multiple lesions occur in patients with neurofibromatosis II and meningiomatosis.^{26,27} Associations have been reported with exposure to ionizing radiation²⁸ and hormonal influences due to the presence of androgen and other hormone receptors.²⁷ They may be locally invasive and the WHO classification of histological findings recognizes three grades (grade 1, benign; grade 2, atypical; grade 3, anaplastic), which are independent of the traditional histopathological descriptions of meningothelial, fibrous, transitional, syncytial and psammomatous subtypes. They are usually highly vascular tumours

with the transitional subtype being most vascular and the psammomatous subtype least vascular.

Clinical presentation varies according to location and imaging by CT scan or MRI is usually adequate for diagnosis and preoperative assessment. Tumour calcification and skull hyperostosis is easier to recognize on CT than MRI and suggest a less vascular subtype. Tumour enhancement after intravenous contrast media administration is typical and is more avid in vascular tumours, but such enhancement does not imply that a particular lesion is suitable for embolization. Treatment is by resection and radiotherapy is reserved for more aggressive histological types. Preoperative embolization is indicated for vascular tumours and for the palliation of inoperable newly diagnosed or recurrent tumours.

Intraarterial angiography is required to assess the extent of tumour vascularity and therefore the potential of embolization. In a minority of tumours, dense calcification on CT or lack of enhancement after contrast media administration imply a less vascular tumour and embolization will not contribute to management, but the majority warrant angiography and possible embolization.

The vascular supply to meningioma is typically arranged in a radial pattern of dilated feeding arteries of decreasing size and a delayed venous phase of contrast passage through the tumour bed. Arterial supply may be from external carotid artery branches or from transpial internal carotid artery branches or a mixture of the two (see **Figure 57.2**). The endovascular therapist therefore needs a detailed preembolization angiogram to evaluate the feasibility (and risks) associated with superselective catheterization and injection of particles. In practice, treatment and catheter angiography are usually combined in the same session and scheduled as part of the patient's overall treatment plan.

Embolization is indicated as an adjuvant to tumour resection in order to reduce operative blood loss and facilitate surgery. Since the typical blood supply is by arteries and arterioles of gradually reducing size, small particles (for example, 150 micron) are used first to obstruct intratumour vessels and larger particles injected subsequently to obstruct larger feeding arteries (see **Figure 57.3**). If embolization is performed preoperatively, this technique will cause acute tumour infarction and swelling should be anticipated. Operation is therefore best performed within hours of embolization or if delayed then steps must be taken to ensure that worsening neurological symptoms or signs are quickly detected and treated. Rarely, tumour necrosis causes bleeding and life-threatening expansion of tumours. This complication occurs in about 1–2 percent of instances. Revascularization of tumour after particulate embolization, due to growth of new vessels and collateral routes of blood supply, can also be anticipated within as short a period as two to three weeks.

Another indication for meningioma embolization is to arrest or impede tumour growth when lesions are

inoperable and radiotherapy inappropriate. In theory, particles delivered into the tumour bed only will cause tissue ischaemia/necrosis without stimulating growth of collateral blood vessels. In this situation, very small particles (50 microns) are injected slowly and no attempt is made to obstruct larger feeding arteries. Tumour devascularization and shrinkage is monitored by MRI enhanced by intravenous gadolinium administration; induced failure of enhancement implying devascularization.

The efficacy of preoperative embolization is difficult to evaluate objectively. Criteria used in reported studies include comparisons of blood transfusion volumes between tumour resection operations performed with or without preoperative embolization, lengths of hospital stay and clinical outcomes. A reduced need for blood transfusion was reported by Teasdale *et al.*²⁹ and Oka *et al.*,³⁰ shorter lengths of hospital admission by Dean *et al.*³¹ and Oka *et al.*³⁰ and improved clinical results by Oka *et al.*³⁰ when adjuvant embolization was performed. A reduction in neurological complications after surgery was reported by Oka *et al.*,³⁰ but this benefit was only evident for patients with large tumours (greater than 6 cm in diameter). The conduct and evaluation of such studies is difficult because of the various sizes and sites of tumours studied.

Several specific complications associated with meningioma embolization have been reported. Intratumoural haemorrhage resulting from devascularization may occur in the 24–36 hours after embolization. In the author's practice, this complication has occurred once in 40 treatments over the last five years. Selective catheterization risks causing vessel damage or rupture. The latter is more likely to occur at sharp bends in vessels. Such bends occur in the course of the middle meningeal artery (a common route for meningioma embolization) and rupture of this artery has been reported to cause bleeding or delayed arteriovenous shunting.^{32,33} The incidence of all procedural complications is about 4 percent, though complications resulting in permanent neurological deficits occur in less than half of affected patients.

Paraganglioma

These benign but locally invasive tumours arise from paraganglionic chemoreceptor cells of neural crest origin. About 50 percent occur in the temporal bone, arising from either the cochlear promontory (i.e. tympanicum) or the jugular bulb (i.e. jugulare), 35 percent in the carotid body, 12 percent in the region of the high cervical vagus and the rest at various sites of the head and neck.³⁴

Though relatively rare tumours, they are usually targets for embolization because of their highly vascular nature. Most occur sporadically though familial cases occur with autosomal dominant inheritance. In approximately 10 percent of patients, tumours are multifocal and

Figure 57.2 Paranasal meningioma. This tumour is supplied by meningeal branches arising from both internal and external carotid arteries. (a) and (b) are lateral views from internal and external carotid injections, respectively. Preoperative embolization of the external carotid supply only was performed. (c) The tumour circulation following selective catheterization of the accessory meningeal artery. The arrow marks the tip of the microcatheter. (d) The effect of embolization on the external carotid angiogram (compare with panel b). (e) and (f) Axial T1W MRI of the tumour before and after embolization of the external carotid blood supply. Note that enhancement occurs in only the medial portion of the tumour on (f) (arrows).

Figure 57.3 Temporal paraganglioma. Lateral angiograms following selective injections into the ascending pharyngeal artery before (a), (b) and after (c), (d) embolization with particles. Images (b) and (d) show the bony details of the digitally subtracted angiograms (a) and (c). The tumour circulation (arrows in (a) and (b)) has been occluded.

up to 5 percent of tumours secrete catecholamines. Symptoms are related to tumour location and typically consist of mass, tinnitus (tympanicum), cranial nerve palsy (jugulare, vagale) and pain. The role of imaging by planar scanning is to support the clinical diagnosis and

usually includes both CT and MRI. The former (performed with high resolution parameters) will best demonstrate bony involvement and MRI will best demonstrate the soft tissue character of tumours. Tumour vascularity and extent can be assessed from scans

performed after intravenous contrast administration and evidence of involvement of the carotid artery or intracranial invasion should be sought. Intraarterial angiography is usually undertaken as part of a preembolization evaluation rather than for surgical planning.³⁵ The typical angioarchitecture of this tumour type makes angiography a very specific diagnostic test and it should be considered prior to biopsy.

On intraarterial angiography, feeding arteries are found to be enlarged and there is an early and intense blush in the tumour bed. The intratumoural angioarchitecture comprises centripetally orientated arterioles estimated to be 90 mm in diameter at the periphery and 300–600 mm in the centre of the tumour with arteriovenous shunts (see **Figure 57.3**).³⁶ To further complicate embolization, the majority of tumours show a multi-compartment pattern of blood supply with arterial and venous supply confined to a haemodynamic unit so that separate injections of embolic agent have to be made into each feeding artery. The technique for embolization has evolved with the development of embolization particles small enough to penetrate the smaller peripheral arteries (see **Figure 57.4**). The presence of intratumour shunts may justify the use of a percutaneous (or intraoperative) direct puncture technique with injections of a liquid adhesive agent (see Tools used in interventional neuroradiology techniques, above) since spread of emboli to the lungs is less likely. However, arteriovenous (AV) shunting is more rare in paraganglioma than within the vascular bed of some other tumour types (for example, nasopharyngeal angiofibroma).³⁷

Embolization is usually performed as an adjuvant to surgical resection. In rare instances, when surgery and/or radiotherapy are considered inappropriate, embolization alone may provide symptomatic relief by stabilizing tumour growth.³⁸ The benefits of preoperative embolization have been demonstrated in several single institution reports.^{39,40} The efficacy of preoperative embolization has

been studied by several groups. Murphy and Brackman compared two groups, totalling 35 patients, and found preoperative embolization reduced the volume of operative blood loss and the lengths of procedure times, but not the length of bed stay.⁴¹ Tikkakoshi *et al.*⁴² reported that preoperative embolization improved operating conditions with subjective benefits to surgical results if performed by superselective catheterization and with effective devascularization of the tumour vascular bed.

EMBOLIZATION FOR EPISTAXIS

Transarterial embolization using particles, coils or balloons has been used to control intractable idiopathic epistaxis. For effective embolization, superselective catheterization of the sphenopalatine artery is performed after lateralization of the bleeding site. This goal is frustrated if prior surgical ligation of the internal maxillary artery has been performed or if the site of bleeding cannot be established. In these situations, particles may need to be injected via both internal maxillary and facial arteries.

There is no consensus on the most effective timing of embolization after the onset of spontaneous epistaxis, and different definitions of intractable epistaxis make it difficult to compare published reports. The vast majority of patients admitted to hospital with epistaxis respond to packing, balloon tamponade or local cautery and only a small minority of patients will need embolization.⁴³ Whether embolization is substantially safer or more effective than internal maxillary artery (IMA) ligation is also debated. In a recent review of the literature comparing embolization with IMA ligation, Cullen and Tami⁴⁴ found that embolization was generally reported to be more reliable, but this was not the case in their institution, where outcomes were similar. However, amongst their patients the procedural complication rate was higher after IMA ligation. If the risks are no greater, then it seems logical to employ embolization first, since IMA ligation limits its subsequent use.

For patients with epistaxis secondary to a vascular malformation or nasal tumour, particulate embolization is indicated to stop acute haemorrhage. In patients with Osler–Weber–Rendu disease, multiple sessions may be required to induce remission and embolization is rarely curative.⁴⁵ In patients with epistaxis due to the rare internal carotid aneurysm or pseudoaneurysm that erodes the sphenoid bone and bleeds intranasally, emergency embolization using coils or balloons can be life saving. Embolization also has a small but important role in the management of patients bleeding as a result of head and neck cancers elsewhere. Haemorrhage may occur from large or small vessels and may be associated with radiation-induced tissue necrosis. A variety of embolization techniques including particles, coils and balloons may be needed to control such bleeding.⁴⁶

KEY POINTS

- Pre-operative embolization should be considered for all vascular tumours.
- Tumour vascularity can only be inferred from CT and MR scans. Intraarterial angiography is still required to identify tumours suitable for embolization.
- Functional testing of vessels 'at risk' during surgery is performed under local anaesthesia by temporary inflation of an endovascular balloon.
- Most embolizations are performed transarterially, but direct percutaneous injections of tumour or vascular malformation vessels or transvenous injections are also possible.
- Embolization alone is used for palliation and management of inoperable tumours.
- Embolization should be considered early rather than late in the management of intractable epistaxis.

probably open new areas of research. The *in vivo* response of lesions will need further study.

Deficiencies in current knowledge and areas for future research

Technical

- Development of non-x-ray imaging. Fluoroscopy using magnetic resonance imaging is now feasible. This avoids the potential hazards of ionizing radiation but requires the development of new catheters and embolic agents. Attempts to develop liquid agents that remain stable in high strength magnetic fields are proving difficult. A great deal of investment is being made to develop ways of monitoring minimally invasive surgical techniques without x-ray fluoroscopy.
- Current liquid embolic agents are adhesive and nonadhesive materials that remain coherent during delivery and are permanent need to be developed.
- Improvements in reliability of data from functional tests are needed. A great deal of research has been directed at the problem of falsely reassuring temporary vessel occlusion tests. A completely reliable protocol is still needed.

Biological

- The evolution of embolized tissue has been studied, but we do not know much about the mechanisms that cause secondary haemorrhage in some tumours.
- The potential benefits of local delivery for gene therapy and future chemotherapy agents will

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words head and neck cancer and photodynamic therapy.

INTRODUCTION

Laser is the acronym for light amplification by stimulated emission of radiation. Surgical lasers are devices that amplify light and create coherent light beams ranging from the infrared to the ultraviolet parts of the spectrum.

HISTORY

In 1917, Albert Einstein described the theory of stimulated emission which is the underlying process for laser action. The American physicists, Arthur Schawlow and Charles Townes, described the working principles of lasers in 1958.¹ In 1960 Theodore Maiman demonstrated the first laser action in solid ruby² and a year later Ali Javan built the first helium-neon gas laser.³ C. Kumar N. Patel introduced the carbon dioxide (CO₂) gas laser in 1962. In 1972, in Boston, USA, Jako and Strong were the

first to pioneer the use of the CO₂ laser in otolaryngology, head and neck surgery.^{4, 5, 6}

PRINCIPLES OF LASER ACTION

A laser empowers atoms to store and emit light in a coherent form. The electrons in the atoms of a laser medium are first pumped or energized to an excited state by an external energy source. These electrons are then stimulated by external photons to emit their stored energy in the form of photons. This process is 'stimulated emission'. The photons emitted have a frequency characteristic to their atoms and travel in step with the stimulating photons. These photons now strike other excited atoms to release even more photons. These photons move back and forth between two parallel mirrors triggering further stimulated emission. This part of the process is known as 'light amplification'. One mirror in the laser tube is partially silvered and it allows the exit or leak of the intense, collimated, monochromatic and coherent laser light.

Nature of laser light

A beam of laser light is:

- **coherent**: the photons or waves travel in step, or in phase with one another.
- **collimated**: the laser light travels in one direction.
- **monochromatic**: one wavelength or colour is in the visible spectrum.

Types of lasers

Depending on the type of laser medium used, lasers can be classified as solid state, gas, semiconductor, liquid or free electron.

A pioneering example of a solid state laser is the ruby laser. The neodymium yttrium aluminium garnate (YAG) laser and the related (frequency doubled) potassium titanyl phosphate (KTP) are examples of solid state lasers in surgical practice.

The carbon dioxide laser (CO_2) is a very efficient gas laser that delivers laser light as an invisible continuous wave beam. The carbon dioxide surgical laser has been the most widely applied laser in oral and laryngological practice. The helium-neon laser is a gas laser with high frequency stability, good colour stability (red) and minimal beam spread. The helium-neon gas laser is often superimposed on an invisible laser beam, such as the CO_2 , to facilitate surgical targetting. Activation of chemicals in photodynamic therapy can be achieved with the helium-neon laser.

The gallium arsenide laser is the most commonly used semiconductor laser. This laser is used in CD players and laser printers and has some surgical applications.

The most common medium for a liquid laser is an inorganic dye contained in a glass vessel. This laser is pumped or energized by intense flash lamps or by a gas laser in a continuous wave mode. The frequency of a tuneable dye laser can be altered with the aid of a prism inside the laser cavity. Tuneable dye lasers can be well suited for treating pigmented cutaneous lesions.

Lasers that utilize beams of electrons unattached to atoms and spiralling around magnetic field lines were initially developed in 1977 and are important research instruments. Free-electron lasers are tuneable and, in theory, could cover the electromagnetic spectrum from infrared to x-rays. Free-electron lasers could be capable of producing very high power radiation and may have medical applications in the future.

Patterns of laser output

The configuration of the resonator cavity and the method in which an energy source is applied to the 'active laser medium' will determine the pattern of a laser output. The

output may be continuous wave or pulsed. A continuous wave laser operates with a constant intensity. A laser that operates with a continuous output for longer than 0.1 seconds is considered a continuous wave laser. A pulsed laser produces a single or train of pulses with each individual pulse less than 0.1 seconds. A Q-switch is an electro-optical component that facilitates the production of a very short (less than 1 microsecond) but high intensity pulse of laser energy.

Basic laser tissue interaction

The reaction of laser energy with living tissue can be photoablative, photochemical, photomechanical or photothermal. Most lasers react with a combination of all these mechanisms although for a specific wavelength and delivery system one form of tissue reaction may predominate.

- **Photoablative** reactions occur when molecular bonds are divided. The ruby laser, for example, can split the molecular bonds of tattoo ink with minimal local thermal damage. Macrophages remove the tattoo ink after the molecular bonds are broken.
- **Photochemical** reactions occur when infrared, visible or ultraviolet laser light interacts with photosensitizers to produce chemical and physical reactions. This forms the basis for photodynamic therapy that is discussed later in this chapter.
- A **photomechanical** effect occurs when the laser energy is pulsed to disrupt tissue or stones by the mechanism of shock waves. An example of this mechanism would be the use of the Holmium YAG laser to shatter ureteric and renal calculi.
- The conversion of absorbed laser light into heat is a **photothermal** reaction. The tissue effect can be cutting, coagulation or vaporization depending on the laser wavelength and the laser delivery device.

LASER LIGHT DELIVERY DEVICES

Many delivery devices are available to deliver laser energy to tissue in a safe and efficient manner. Some delivery devices are suited ideally for the wavelength that they transmit. Examples of delivery systems would be an articulated arm, a mirror lens system, micromanipulator, fiberoptic fibre, shaped tip fiberoptic fibres and robotized scanners.

An articulated arm uses a system of hollow tubes and mirrors to direct the laser beam to the target area. Most articulated arms have a lens system to focus the emerging beam on the target tissue. The carbon dioxide laser wavelength is absorbed in fiberoptic material and hence this laser energy is delivered with an articulated arm system.

Micromanipulators and other focussing devices can be connected to microscopes. Micromanipulators and focussing devices will create an accurate and reproducible spot on target tissue. This facilitates very accurate multiple laser strikes which is important in otology and laryngology.

Laser energy exits from a micromanipulator or focusing device in a similar style to the 'laser beam weapon' of science fiction. This means that inadvertent strikes beyond the target tissue or misdirection from a reflective surface are a significant operative risk. It also means that a 'laser beam' can be deliberately redirected by a mirror. An example of this would be to use a mirror to redirect CO₂ laser energy on to adenoid tissue or on to lymphoid tissue on the base of the tongue.

The bare fibreoptic fibre is the most common technique for delivering laser energy to tissue. The flexibility and diameter of fibreoptic fibre facilitates their use with both rigid and flexible endoscopes. This means that laser energy can be delivered to almost any tissue that can be seen with an endoscope.

The tissue response to laser energy exiting from the tip of a fibre can be controlled by altering the distance of the fibre from the tissue. Changing the distance between the fibre and the tissue can produce all the tissue photo-thermal effects of coagulation, incision and vaporization. Laser light exits the tip of the fibre in what is called the 'angle of divergence'. The light exiting from the tip of the fibre projects in a similar manner to water projecting from the nozzle of a hosepipe. The smallest light spot and, consequently, the highest concentration of energy are found at the fibre tip. As the distance from the fibre to tissue increases, the projected area of light decreases and the energy intensity reduces.

A fibre 'in contact' with tissue will create an incision. The cut is similar to a saw rather than a knife. This means that some tissue is removed like the kerf of a saw as compared to being split with a scalpel. There is a degree of tactile control with a laser fibre 'in contact' mode. As the fibre is retracted and hovers above the tissue (2–4 mm), it is in the 'near contact' position and vaporizes tissue. As the laser fibre is retracted even further from tissue into the 'noncontact' mode, then the tissue effect is coagulation.

A fibreoptic laser cable can be inserted through the biopsy channel of a fibreoptic endoscope. The end of the laser fibre must protrude beyond the end of the endoscope or heat damage to the endoscope can occur when the laser is fired. To simplify this problem one can perform a preliminary check of the length of fibre required to achieve a satisfactory distal position and then mark the laser fibre with a 'steristrip' at the entry port.

A fibreoptic laser fibre can be inserted through a narrow metal tube to help direct the laser energy. In otology, for example, the laser fibre can be presented through a hollowed out needle. An aspiration channel can be added to the hollow metal fibre carrier to remove smoke from the surgical site. Figure 58.1 shows a

modified ear suction tube and fibre holder that is used for endoscopic intranasal surgery. In the design of these instruments, the curves of the fibre carrier should create sufficient resistance that when combined with the torque of the laser fibre it results in a fibre that is 'held' in position without any additional mechanism. In Figure 58.2, the 0.6-micron laser fibre can be set at the position of choice for the surgeon and will not move unless the surgeon applies additional pressure. The indent of the finger shows the pressure to overcome the self-retaining torque.

A shaped tip laser is a laser fibre with a tip constructed of another material, such as metal or synthetic sapphire. The laser energy heats the tip and it is the conduction of heat from the tip that produces the tissue interaction. Different materials and shapes of tip will create different tissue reactions. Some tips become so hot that a secondary cooling mechanism is required. An example of this type of device in head and neck practice would be a sapphire tipped neodymium YAG fibre used to ablate tracheobronchial tumours.

Robotized scanners can facilitate laser treatment by reproduction of previous instrument settings or by being able to control precisely the distance a laser is placed or 'hovered above' the target tissue. A robotized scanner can 'trace' an area of treatment before delivery of laser energy to ensure accuracy or can apply a pattern to the area of laser treatment. At present, the greatest use for robotized scanners is in the cutaneous treatment of pigmented lesions and for skin resurfacing or recontouring.

LASER-TISSUE INTERACTION

When laser light strikes tissue, it scatters until all the laser energy is either absorbed or reflected. The absorption of laser energy heats tissue. The volume of tissue affected is larger than the area shown by the laser spot size. The depth of penetration by a given wavelength of laser light is determined by the absorption and scattering of the type of tissue and the wavelength of the laser.

The strength of the tissue effect is altered by changing the fluence. Fluence is defined as the laser power in watts, multiplied by the length of exposure in seconds, divided by the area (mm^2) of the target tissue. This implies that when the distance between a fibreoptic tip and the tissue varies, the spot sizes becomes bigger or smaller and the fluence will accordingly increase or decrease.

The heat in the tissue produces a series of changes in the tissue as the temperature rises. The changes are denaturation, coagulation, vaporization, carbonisation and incandescence. Cutting with a laser is narrow controlled vaporization! The heat produced by the absorption of laser light is partly dissipated into air but also produces a secondary thermal effect in surrounding tissue. This lateral thermal effect produces haemostasis by coagulation. The lateral haemostasis effect varies with wavelength of laser, the rate at which the energy is applied, fluence and the nature of the tissue.

LASER APPLICATIONS IN OTOLARYNGOLOGY

The specific clinical applications of lasers are not described in this chapter, but the following list identifies particular lasers for disease-specific regions:

- stapedectomy and tympanomastoid surgery: carbon dioxide laser, KTP laser, argon laser;
- endonasal dacryocystorhinostomy: Holmium YAG laser, KTP laser, 810 nm laser;
- nasal and sinus surgery, including tumour surgery, telangiectasia destruction, antrostomy creation and turbinate reduction: Holmium YAG laser, KTP laser, Nd YAG laser, argon laser, 810 nm;
- nasal polyp reduction: CO₂ laser 'swiftlase' (oscillating device).

LASER SAFETY

Each country applies different safety regulations throughout the world. Usually the Medical Devices Agency of a country or state will produce guidance for clinicians and hospitals. In the UK, the local Medical Physics Department will produce local laser rules (based on national guidance) and ensure training of all staff involved in the use of the laser. Training for medical and nursing staff should be mandatory. A laser company will typically provide a safety manual on their particular wavelength of laser. Staff should read the laser safety manual and in many countries produce signed documentation that the manual has been read.

The principles of safety are as follows.

- A laser beam may hit or damage objects outside the target area and cause a fire, tissue damage or eye/visual damage.
- The patient should be shielded by wet gauze or fireproof material from accidental strikes.
- The anaesthetic tube and airway should be protected from accidental strikes that could produce a fire.
- All personnel in the operating room should wear correct eye protection appropriate to the wavelength of the laser.
- A warning sign plus locked doors should prevent unprotected and unprepared individuals from walking into the operating room when the laser is in use.
- The key to switch on the laser should be held by a senior member of the operating team to ensure only properly qualified individuals use the laser.
- The operating room and windows should be laser protected.
- Endoscopic equipment should be blackened to reduce accidental reflective strikes of the laser.

PHOTODYNAMIC THERAPY IN OTORHINOLARYNGOLOGY

Principles of photodynamic therapy

Phototherapy is the use of light in the treatment of disease. An example would be the treatment of neonatal hyperbilirubinaemia with visible light.

Photochemotherapy is a subset of phototherapy where a treatment requires the administration of a drug in addition to the application of light. An example would be treatment of a skin condition such as psoriasis with the combination of a furocoumarin sensitizer drug and UV-A (320–400 nm) light.

Photodynamic therapy (PDT) is a subset of photochemotherapy where, in addition to an administered drug and the application of light, oxygen is required to complete the process. The administered drug is known

as a 'photosensitizer'. This type of drug accumulates within a cell and reacts with light and oxygen to form 'singlet' oxygen. The 'singlet' oxygen damages the cell membranes and produces cell death.

One of the attractions of PDT for oncology is that the photosensitizer drug is typically retained in tumour tissue for a longer period than in normal tissue. This improves the therapeutic effect while reducing toxicity to normal tissue. The use of PDT is not affected by prior radiotherapy, chemotherapy or surgery. To date, the principle shortcomings of PDT have been the limited depth of tissue penetration and extensive skin phototoxicity. This skin phototoxicity requires that the patient is not exposed to daylight during treatment or they develop extensive and painful skin reactions.

In photodynamic therapy for head and neck cancer the photosensitizer is usually administered by intravenous infusion. The perfect photosensitizer drug would be absorbed selectively only by tumour tissue in the drug uptake period (also called the drug-light interval). The drug uptake period may last between 3 and 96 hours. The tumour is then irradiated with a measured light dose. Singlet oxygen is released to kill only tumour cells and thus destroy the target tumour.

The tumour targeting arises firstly from the structure of the photosensitizer that leads to the selective uptake by a tumour and secondarily by the accurate application of an appropriate light wave.

The diseases in which trials of photodynamic therapy have taken place include malignant tumours, such as squamous carcinoma of the oral cavity, squamous carcinoma of the nasopharynx, oesophageal carcinoma and metastatic squamous carcinoma of the neck. Non-malignant disease such as inverted papilloma of the sinonasal cavity has also been targeted.

Photodynamic clinical reports in otorhinolaryngology

Both palliative and curative therapy has been reported for oesophageal cancer. The patients receive a photosensitizer followed by light delivered via optical fibres through a flexible endoscope. A phase II trial⁷ randomized 218 patients to receive palliative oesophageal PDT (porfimer sodium sensitizer) versus Nd:YAG laser ablative therapy. Each arm gave an equivalent improvement in dysphagia but with fewer perforations in the PDT group (1 versus 7 percent, $p < 0.05$). [***]

Overholt and Panjehpour⁸ reported the results of 55 patients with dysplasia or early carcinoma in Barrett's mucosa of the lower end of the oesophagus treated with PDT. The patients received porfimer sensitizer followed at 48 hours with red light therapy. There was a good response at the six-month follow up. Forty-three patients with high-grade dysplasia/adenocarcinoma had endoscopic-proved ablation of their problem. Eleven of the 12

patients with low-grade dysplasia had no dysplasia on endoscopic review. Oesophageal stricture, however, developed in 53 percent of the patients. [***]

There has been hope for PDT in the treatment of head and neck tumours (See Chapter 188, Nasopharyngeal carcinoma; Chapter 192, Oral cavity tumours including the lip; and Chapter 194, Tumours of the larynx). The endoscopic access to squamous tumours of the upper aerodigestive tract combined with the tendency to develop 'field cancerization' make these tumours good candidates for PDT. Gluckman⁹ treated a mixture of carcinoma *in situ*, early and advanced squamous cell carcinoma of the head and neck. Dihaematoporphyrin ether and light at 630 nm were used to treat these patients. The best results were obtained in the oral cavity and oropharynx where 11 out of 13 patients had a complete response and two out of 13 a partial response. Four of these tumours had recurrence within one year of treatment. Eight patients with advanced tumours were treated palliatively, but the results were no better than with standard regimes of the time. [**]

Biel¹⁰ treated 25 patients with early squamous cell tumours of the larynx, obtaining a complete response in patients despite the fact that radiation therapy had previously been unsuccessful in 17 of them. [**]

Biel¹¹ also reported a summary of the results of a collection of studies on the treatment of early squamous cell carcinoma of the head and neck with PDT. There were a total of 217 patients. One hundred and ninety-four (89 percent) showed a complete response to treatment, 23 (10.6 percent) showed a partial response and no patient failed to show any response to the therapy. [**]

Dilkes *et al.*¹² had considerable experience with the use of PDT using the sensitizers m-TPHC, photofrin II and ALA for squamous carcinoma at multiple sites in the head and neck during the mid-1990s. The patients they treated included palliative, primary and adjunctive forms of treatment and, in nearly all cases, the authors identified a visible response to the effects of PDT. Their complications included local pain at the photosensitizer injection site and, in some patients where appropriate precautions had not occurred, post-treatment skin photosensitivity. [**]

Lofgren *et al.*¹³ used PDT in five patients with circumscribed nasopharyngeal carcinoma. The drug was activated with laser light under topical anaesthesia and after four years, three of the patients has no evidence of disease. [**]

KEY POINTS

- Light amplification by stimulated emission of radiation.
- Laser light – collimated, coherent and monochromatic.
- Laser tissue action – photoablative, photochemical and photomechanical.

- Laser 'star wars' beam of micromanipulator – hosepipe type jet of fibreoptic laser delivery.
- Read and follow the safety regulations for your laser and operating room.
- PDT requires administered drug, light and oxygen.
- Skin phototoxicity and limited tissue penetration are the current PDT shortcomings.
- PDT has a future place in head and neck cancer management.

Deficiencies in current knowledge and areas for future research

All of the papers on photodynamic therapy for head and neck cancer suggest that photodynamic therapy has a significant place in the future management of this disease. The problem is in determining the exact type of photodynamic therapy associated with which photosensitizer and whether primary therapy, adjunctive therapy or palliation is the optimum course.

SEARCH STRATEGY

The information presented in this chapter is supported by a Medline search using the key words intraoperative monitoring, facial nerve, cranial nerve and auditory evoked potentials.

DEVELOPMENT OF FACIAL NERVE MONITORING

The first description of intraoperative cranial nerve stimulation was by Fedor Krause in 1898.¹ During cochlear nerve section for tinnitus, he noted '... unipolar faradic stimulation of the (facial) nerve-trunk with the weakest possible current of the induction apparatus resulted in contractions of the right facial region, especially of the orbicularis oculi, as well as the branches supplying the nose and mouth'. Over the next three-quarters of a century, a series of articles refined the technique, all relying on observing movement of the face in order to confirm the functional integrity of the facial nerve.^{2, 3, 4, 5, 6, 7} The evoked facial twitch was observed either by the anaesthetist or ancillary staff under the drapes using a flashlight or mirror. These techniques lacked both quantitative control of the stimulus and objective recording of the evoked responses.

In 1979, Delgado and colleagues first described the use of evoked compound muscle action potentials (CMAP) to monitor facial nerve function in response to stimulating

the intracranial portion of the facial nerve.⁸ The introduction of facial electromyography (EMG) enabled not only facial nerve identification either by electrical stimulation or inadvertent manipulation, but also the possibility of mapping its course through the temporal bone and assessing changes in function during surgical resection of tumour from the nerve's surface.⁹ Facial nerve monitoring has proved an invaluable aid during vestibular schwannoma surgery.^{10, 11, 12} The introduction of an auditory signal enabled instantaneous real-time auditory feedback to the surgeon during tumour dissection without information passing through an intermediary.^{13, 14}

Three trials tested the hypothesis that facial nerve outcome improved when using intraoperative facial nerve monitoring. Harner and colleagues¹² demonstrated the usefulness of facial nerve monitoring in 91 consecutive cases of vestibular Schwannoma resection via the suboccipital route. At one year, 78 percent of those patients who were monitored demonstrated facial function, compared with 65 percent in an unmonitored group, these data were not studied statistically. Niparko and colleagues¹⁵ described the results of 29 patients who

underwent translabyrinthine removal of vestibular Schwannoma and compared them with a similar group of 75 unmonitored patients. They demonstrated that monitoring was associated with a significant improvement of facial function at one year for tumours over 2 cm intracranial diameter. Kwartler and colleagues¹⁶ demonstrated that monitored patients with tumours over 2.5 cm had a significant improvement of facial function when compared with a matched unmonitored group. [**]

The benefit of facial nerve monitoring during surgery for chronic middle ear disease is less certain. Facial nerve injury after otological surgery is rare in experienced hands and there are no randomized controlled trials examining its efficacy. Silverstein and others recommend that the facial nerve should be monitored during all general anaesthetic cases where the facial nerve is at risk.^{17, 18} This view is in contrast to most American otolaryngologists, although those that trained in the 1990s, those in an academic setting and those who perform more otology than other types of surgery are more likely to use monitoring techniques.^{19, 20}

Facial nerve injury often occurs when there is an unexpected change to normal middle ear anatomy, precisely the time when monitoring is so valuable. The senior surgeon must take responsibility to ensure that the equipment is functioning normally. A simple technique for confirming equipment function is described under Technique for continuous facial nerve monitoring. Intraoperative facial nerve monitoring is no substitute for experience in the otological setting and should not replace good surgical practice, but if the operating team adopt the approach that all patients are monitored, the set up technique becomes routine and more reliable.

TECHNIQUE FOR CONTINUOUS FACIAL NERVE MONITORING

The operating theatre is filled with electrical interference generated by the equipment surrounding the anaesthetized patient. Monitoring techniques have developed to minimize this interference and amplify only relevant information. Two sets of subdermal platinum or stainless steel needle recording electrodes are inserted into the upper and lower face. The amplifiers amplify the difference between the potentials recorded at each electrode. This arrangement has the advantage of common mode rejection; electrical interference from other sources is recorded by both electrodes equally and therefore does not create a potential difference between the two closely aligned electrodes. A number of commercial EMG cranial nerve monitoring systems are now available including the NIM-2 (Xomed Treace, Jacksonville, FL, USA) and the Neurosign (Magstim, Whitland, UK). They rely on recording facial muscle activity and delivering the information as a visual and audible representation of the CMAP response. The audible response is either presented as raw EMG activity or a

characteristic sound when EMG activity reaches a set threshold.

All systems are isolated and self-contained electrical nerve stimulator and monitoring units. The electrodes are connected to a preamplifier pod, which is attached to the operating table. The recorded electrical signal is filtered through high- and low-pass filters and either rectified and displayed on a logarithmic bar chart or presented as a CMAP waveform. Different systems use different methods of presenting the same information to the surgeon. The logarithmic bar chart has a delayed response decay to enable calculation of rectified CMAP amplitude. Systems that present a CMAP waveform present it as visual and audible real-time information or utilize image capture strategies that also give waveform amplitude information. This allows the surgeon time to examine the waveform and size of the CMAP.

Familiarity with the set up and function of a chosen monitoring system is essential. The senior surgeon must take responsibility and should check that the equipment is functioning normally. Tapping the skin overlying the two sets of subdermal electrodes will generate a recorded response on the monitor. This confirms that electrodes are connected to the preamplifier pod and in turn the preamplifier pod is connected to the monitor, which is switched on. The volume should be checked so that a response is audible over background theatre noise.

Facial nerve stimulation is delivered as a short (0.1 ms) electrical pulse. The stimulating electrode is either monopolar or bipolar. The monopolar electrode is favoured because it is simple to use, but has the disadvantage of stimulating a larger area. The bipolar electrode requires careful positioning of both electrode tips on to the tissue surface; this can prove difficult in the tight confines of the temporal bone. The use of constant voltage stimuli has an advantage over constant current stimuli because it delivers a relatively reliable current to the nerve whatever the medium that surrounds the nerve.

PREDICTING POSTOPERATIVE FACIAL FUNCTION

Recently, a number of studies have described an objective technique that correlates parameters of the evoked CMAP to eventual facial outcome.^{15, 21, 22, 23, 24} The test gives non-dichotomous results and therefore a retrospective cut-off point is used to predict those patients who have a good prognosis. Results indicate that a low stimulation threshold, across the site of tumour dissection, is a valuable prognostic indicator of good long-term facial function. The technique, which is simple to perform, assesses the minimum current required to evoke a muscle response after tumour resection. The drawback to the described technique is that the majority of patients have some degree of facial function immediately after surgery. This group will almost certainly have good long-term outcome.²⁵ It is

the small group of patients with poor facial function immediately after surgery that will benefit most from a sensitive and specific predictive test. Axon and Ramsden compared post-dissection minimal stimulation thresholds with immediate postoperative facial function for predicting long-term facial function in 184 patients undergoing vestibular Schwannoma surgery.²⁵ Post-dissection stimulation thresholds demonstrated only a moderate relation to eventual outcome, which was of limited clinical value. The test criteria were then applied to patients with poor immediate postoperative facial function for predicting long-term outcome, the predictive accuracy fell, further reducing test validity. [**]

Some studies compared the supramaximal CMAP to either facial nerve stimulation proximal and distal to tumour dissection or before and after tumour dissection. These techniques have been advocated as more accurate methods of analysing data, because they remove absolute amplitude comparisons and rely on comparison of ratios.^{26,27} [**]

DIFFICULTIES OF MONITORING FACIAL FUNCTION

All otological procedures rely on a facial muscle response, warning the surgeon that the facial nerve is near. A simple audible noise is all that is required. Recent monitoring systems have increased the amount of information available to the surgeon, stimulating the desire to expand monitoring techniques and so improve patient outcome. This information is superfluous to most procedures and of benefit to only a few. Facial CMAPs represent a complicated interplay between groups of muscle fibres depolarizing in response to facial nerve stimulation. The muscles of the face are very different to those found in the limbs. The facial motor units are small, often having only 25 muscle fibres supplied by each motoneuron compared with many thousands in more peripheral muscles. As a consequence, each muscle has a wide ill-defined motor end-plate zone. The muscles are also arranged in an almost haphazard arrangement, overlying each other and aligned in different directions. This makes meaningful electrophysiological recording difficult. Intra-subject variability (test-retest variability) is high and intersubject comparison almost impossible. The CMAP waveform is usually multiphasic instead of the well-recognized biphasic responses recorded from peripheral muscles, a consequence of phase cancellation. Calculation of maximum amplitude or area under the waveform bears little relation to the number of motoneurons innervating the muscle fibres that create the response.

MONITORING FACIAL FUNCTION FOR NONOTOLOGICAL PROCEDURES

The facial nerve is at risk of iatrogenic injury in the cerebellopontine angle and parotid. Intraoperative facial

nerve monitoring has been advocated during microvascular decompression and superficial parotidectomy.^{28,29} Arguments for adopting its use for all surgical procedures are the same as those for otological surgery.

MONITORING AUDITORY FUNCTION

The aim of monitoring the status of the auditory pathway during cerebello-pontine angle (CPA) surgery is the prevention of avoidable postoperative hearing deficit. The achievement of this laudable aim is fraught with difficulty. The cochlear nerve is sensitive to mechanical manipulation and easily damaged, as the intracranial section of the nerve is sheathed in central myelin and has no perineurium.³⁰ Additionally, the cochlear nerve is intimately involved with pathologies, such as vestibular schwannoma, and hence at very considerable risk during the surgical removal of such lesions, even when every care is taken to preserve the nerve anatomically. The basic principle of intraoperative monitoring is that changes in recordable neuroelectric potentials occur whilst the injury is still reversible and before permanent deficits result.³¹ Recent research³² has demonstrated that this principle holds for changes in auditory brainstem responses (ABR) wave V amplitude (and to a lesser extent latency) in rat auditory nerves manipulated in a fashion analogous to that undergone in humans during vestibular schwannoma removal. It is therefore theoretically feasible that monitoring auditory function may inform the surgeon of reversible injury to the cochlear nerve.

One prerequisite of monitoring auditory function during surgery is that sufficient preoperative hearing must remain such that meaningful recordings may be made in the operating theatre and change observed if and when it occurs. If ABR or electrocochleography (EcochG) are the monitoring techniques of choice, a further prerequisite is for preoperative recordings with that technique. Monitoring with ABR is not possible if waveforms are absent or of grossly abnormal morphology.

Whilst the techniques and equipment utilized for auditory monitoring may seem familiar from the outpatient clinic, their use in monitoring is significantly different. Rather than comparing an individual's data with group data, in monitoring one is comparing a sequence of waveforms over time and evaluating for change. The time allowed for eliciting each recording is limited and this will influence the choice of recording parameters. The decision whether to inform the surgeon of a change in recorded activity is both urgent and crucial. As such, the person undertaking monitoring should be familiar with the operating theatre environment and team, and be able to interpret and communicate observed and measured change to the surgeon confidently and concisely.³³ Such skills are rare and this may prove to be a hindrance to the widespread adoption of these techniques.

TECHNIQUES

Otoacoustic emissions

Cane *et al.*³⁴ undertook a feasibility study of the use of otoacoustic emissions (OAE) as a technique for monitoring the auditory pathway during surgical removal of a vestibular schwannoma. The experience was that OAE recordings were feasible despite the noise within the surgical environment, but the study did not indicate that OAE would be a useful indicator of early, reversible injury. Theoretically, OAE recording may furnish evidence of cochlear function, but as the site of surgery is the internal auditory canal (IAC), one would not be measuring activity deriving from the point of possible injury. OAE monitoring might therefore give information about ischaemic or noise injury to the cochlea, but it has not yet been demonstrated that this would be at a point where the injury was reversible. At the present time, however, the use of OAE in monitoring auditory function during surgery is rare.

Electrocochleography

Similarly, electrocochleography records activity associated with cochlear function and the distal portion of the cochlear nerve, rather than the intracranial portion of the cochlear nerve, which is acutely at risk during surgery. As such, even strong advocates of EcochG in monitoring have seen it as adjunct to ABR, and not providing the surgeon with the required information when used alone. There is research evidence that responses to auditory stimulation recorded by EcochG persist after complete transection of the VIIIth nerve in the rat,³⁵ and so this technique has the potential to mislead if used in isolation.

One potential advantage of the use of EcochG is the large amplitude of the activity recorded.³⁶ This allows interpretation of the elicited waveform after fewer averages, so that decision-making may be more rapid.³⁷ As with EcochG in the outpatient context, there is debate about the optimal site of the recording electrode, with advocates for extratympanic intrameatal placement³⁶ and transtympanic placement.³⁸ A further advantage is that EcochG recordings are less compromised by acoustic noise or by electrical artifact as may occur during cautery, and may serve some purpose whilst these are present.³⁹

Auditory brainstem responses

Auditory brainstem responses have a theoretical advantage over other techniques in that certain peaks within the waveform derive from anatomical structures at risk of injury during surgery. The generator of wave I is considered to be the distal portion of the cochlear nerve, the site also held to be the generator of the N1 component

of the compound action potential recorded by EcochG.³⁰ Wave II is associated with the proximal section of the cochlear nerve,³¹ wave III with the lower pons (specifically the superior olivary complex)⁴⁰ and wave V with the inferior colliculus.⁴⁰ The generators of waves III and V are, therefore, unlikely to be directly challenged by surgical manipulation during hearing preservation surgery for space occupying lesions of the CPA, but the latencies of these easily identifiable waves are used during monitoring as change reflects latency change of waves I and II.

Specific methodologies and parameters utilized in intraoperative ABR have been described in detail. The reader who intends to perform this procedure is directed to the comprehensive reviews by Moller³¹ and Martin and Mishler.³⁰ Several points should be noted. There is considerable variability in the methods advocated and clinical trial evidence is not apparent. Second, this variability may account in part for the lack of a strong evidence base for the benefits of auditory monitoring. Further, the reviews cited underline the difference between utilizing ABR in the outpatient clinic and the operating theatre, the need for the technique not to inconvenience surgical techniques and the utility of clear and timely interpretation and communication of change in recordings to the surgeon.

Direct recordings from the cochlear nerve

The need for rapid acquisition of responses may be met by recording directly from the cochlear nerve, the large amplitude of the elicited activity obviating the need for lengthy averaging.⁴¹ This technique was first developed to monitor cochlear nerve function during microvascular decompression surgery, but has been adapted for use during surgical removal of space occupying lesions of the CPA.³⁷ The site of recording is usually the root entry zone, and both monopolar and bipolar electrodes have their advocates.⁴² Click stimuli similar to those used in ABR are used to elicit the response, which comprises a compound action potential. Changes in latency, amplitude and morphology should all be reported to the surgical team.³¹

Combining techniques

Given that each of the techniques described above has technical challenges and shortcomings, many teams choose to utilize more than one, the most common combination being direct cochlear nerve recording and ABR.⁴³

EVIDENCE OF THE EFFICACY OF MONITORING AUDITORY FUNCTION

Authors have reported hearing preservation rates following vestibular schwannoma excision, but the heterogeneity

of pathological status, surgical technique, surgical experience and criteria for reporting of hearing preservation combine to frustrate analysis of the clinical utility of auditory monitoring. Observational evidence in this area abounds.^{44, 45, 46} The need for well-designed, hypothesis-driven clinical trials in this field is paramount.

A similar dearth of evidence is found when determining the relative efficacy of techniques or combinations of techniques. Several studies have reported that direct cochlear nerve recordings are more effective in the maintenance of hearing function than ABR, to an extent that is statistically significant.^{47, 48} This effect is said to be due to the immediacy of direct recordings.⁴⁹ [**]

Despite the lack of evidence, a consensus is building that monitoring auditory function during CPA surgery is best practice,⁴² and that a combination of ABR and direct cochlear nerve recording is optimal,³⁵ with the adjunctive use of EcochG if desired.³⁸

KEY POINTS

- Monitoring facial nerve function is straightforward and neither hampers nor impedes surgery.
- There is a good evidence that monitoring facial nerve function improves outcomes of facial function.
- A consensus has not yet been reached on techniques for monitoring auditory function, but it looks likely that a combination of techniques will be optimal.

Best clinical practice

- ✓ Regarding monitoring of facial nerve function, there is evidence that these techniques offer benefit in improving facial nerve outcomes in surgery that may challenge the facial nerve. As such it is strongly indicated. [Grade B]
- ✓ The evidence base for monitoring auditory nerve function is less robust, but it should be regarded as best clinical practice [Grade D/C].

Deficiencies in current knowledge and areas of future research

- Further work is required to develop an intraoperative technique that enables accurate assessment of clinical facial nerve function at any point during skull

base procedures. Only accurate estimation of motoneuron function will give the surgeon a true representation of immediate facial function and hopefully then enable development of a valid predictive technique.

- The speciality as a whole requires a good evidence base to support the use of intraoperative facial nerve monitoring as the standard for all otological procedures that place the facial nerve at risk.

SEARCH STRATEGY AND EVIDENCE-BASE

The data in this chapter are supported by a PubMed search using the key words optical coherence tomography, needle biopsy, surgical guidance, nasal, vocal cord and/or otology. Levels of evidence are not really applicable to this area, but the human studies that underlie the discussion of optical coherence tomography as applied to otorhinolaryngology are observational or at best non-randomized.

INTRODUCTION

Medical imaging technology has advanced rapidly over the past twenty years, providing physicians with essential information on the macroscopic anatomy of patients. Techniques capable of imaging subepithelial structure *in situ*, such as conventional x-ray radiography, magnetic resonance imaging (MRI), computed tomography (CT) and ultrasonography have allowed the noninvasive investigation of relatively large-scale structures in the human body, with resolutions ranging from 100 μm to 1 mm. Resolution on this scale, however, is insufficient to detect the subtle changes in tissue microstructure characteristic of many ear, nose and throat (ENT) pathologies.

In the field of laryngology, light endoscopy currently forms the cornerstone of clinical imaging and biopsy guidance, yet conventional light endoscopic techniques are unable to reveal information concerning subepithelial tissue. Since many laryngeal pathologies originate near the boundary between the epithelium and the underlying mucosa or within the mucosa itself, the inability to image subepithelial tissue represents a serious limitation of

conventional light endoscopy. Even as a method for guiding biopsy, conventional light endoscopy gives only a relatively coarse indication of prospective biopsy locations. Frequently, a large number of biopsies are required to achieve high diagnostic accuracy, a situation that is often undesirable or unfeasible. This is particularly true for the vocal folds, which have a specialized and delicate microstructure that is highly intolerant of trauma. These limitations restrict the effectiveness of light endoscopy for the diagnosis, monitoring and treatment of many laryngeal pathologies. Clinical laryngology would thus greatly benefit from a noninvasive imaging technology capable of resolving subepithelial tissue microstructure in the range of conventional biopsy.

Optical coherence tomography (OCT) is a relatively new optical imaging modality that allows high-resolution, cross-sectional imaging of tissue microstructure. OCT can image with an axial resolution of 1–15 μm and has an imaging depth of 2–3 mm in nontransparent tissue. OCT was first applied in 1991 to imaging optically transparent structures, such as the anterior eye and retina.^{1,2} Subsequent technological advances have enabled high-resolution

imaging of nontransparent tissue in the cardiovascular system³ and the gastrointestinal,⁴ urinary⁵ and female reproductive tracts.⁶ In addition, the application of OCT to surgical guidance⁷ and carcinoma detection^{6,8} has been explored.

The aforementioned imaging studies have demonstrated that OCT is particularly informative in tissues in which nonkeratinized epithelium is separated from underlying stroma by a smooth basement membrane zone, suggesting that OCT may have a strong clinical relevance in laryngology. This indication is further strengthened by several features of the OCT system itself.

- OCT imaging can be performed *in situ* and nondestructively, enabling the imaging of tissue for which biopsy should be avoided or is impossible.
- OCT images are high resolution, 10–100 times that of conventional MRI or ultrasound.
- Imaging can be performed in real time, without the need to process a specimen, as in conventional biopsy, and without the need for a transducing medium, as in ultrasound imaging.
- OCT is fibreoptically based and can thus be interfaced to a wide range of instruments including catheters, endoscopes, laparoscopes and surgical probes.
- OCT systems can be engineered to be compact, portable and low cost, depending on the desired system specifications.

Although this chapter will focus primarily on the potential applications of OCT to laryngeal tissue, OCT has also been applied to imaging of the middle ear⁹ and of rat cochlea¹⁰ *ex vivo* with promising results. In addition, OCT has strong potential for improved visualization of nasal tissues.¹¹ Before presenting and discussing OCT images of larynges *ex vivo*, it is useful to briefly describe the basis by which OCT systems form subepithelial images.

OPTICAL COHERENCE TOMOGRAPHY: SYSTEM OPERATION

Optical coherence tomography performs high-resolution tomographic imaging by measuring light backscattered or backreflected from internal tissue structures. OCT imaging is analogous to ultrasound B-mode imaging, but is based on the detection of infrared light waves, instead of sound. Like acoustic waves, light is characterized by its propagation direction. Light is distinct, however, in that it has an additional vector characteristic known as polarization. The polarization direction is orthogonal to the propagation direction and can be influenced by the medium in which the light propagates. This is known as 'birefringence'. Polarization measurements can be used to provide additional insights into the microscopic structure and integrity of tissues. An adjunct

to conventional OCT, polarization-sensitive OCT (PS-OCT), exploits birefringence as an additional contrast mechanism for imaging tissue. PS-OCT will be discussed in further detail under Polarization-sensitive optical coherence tomography.

The analogy with ultrasound is a useful starting point for understanding the basics of OCT. In ultrasound, a high frequency acoustic pulse travels into the tissue and is reflected or backscattered from internal structures having different acoustic properties. The magnitude and the delay time of the echoes are electronically detected, and the structural properties of the internal tissues are determined from the measured signals. In OCT, imaging is performed by measuring the echo delay time and magnitude of light backreflected or backscattered from internal structures with distinct optical properties. Unlike in ultrasound, though, the speed of light is very high, rendering electronic measurement of the echo delay time of the reflected light impossible. OCT systems circumvent this limitation by using low coherence interferometry, also known as white light interferometry, to characterize optical echoes.

The most common OCT echo detection scheme is based on a Michelson interferometer set up with a scanning reference delay arm, shown in **Figure 60.1**. Within the interferometer, the beam leaving the optical light source is split into two parts, termed the reference and sample beams, at the beam splitter. The reference beam then travels to a mirror, located at a known distance from the detector and subsequently returns to the beam splitter. The sample beam travels to the tissue sample and is reflected back toward the detector by scattering sites within the tissue. Light reflecting from deeper tissue layers has traversed a greater optical pathlength (optical distance) and therefore arrives at the detector at a later time. In addition, the various backreflected parts of the sample beam will have different amplitudes based on the

Figure 60.1 Schematic of an optical coherence tomography system using a Michelson interferometer with scanning reference delay arm.

differing strengths of the scattering sites. The reflected portions of the sample beam then return to the beam splitter where they interact with the reflected reference beam and are directed toward the detector.

When two waves from the same source recombine in this manner, an interference pattern will result if the optical pathlength travelled by the two waves is identical. The output detector measures the intensity of this interference pattern and thus only measures information contained in the portion of the sample beam that has travelled the same optical distance as the light in the reference arm. Information about the remaining tissue layers can be extracted by moving the mirror in the reference arm, which changes the optical pathlength travelled by the reference beam. Two- or three-dimensional images are produced by scanning the beam across the sample and recording the optical backscattering versus depth at different transverse positions. The resulting data is a two- or three-dimensional representation of the optical backscattering of the sample on a micron scale.

OCT IMAGING OF THE LARYNX: PRELIMINARY RESULTS

To assess the potential value of OCT imaging technology in improving visualization and pathology, diagnosis and treatment of a given organ system, it is essential to first image normal tissue from that particular organ and then reference the resulting OCT images to parallel histology.

Initial studies of the laryngeal imaging using OCT^{12, 13} have focused on the following structures due to clinical relevance:

- the laryngeal surface of the epiglottis;
- the false folds;
- the inferior surface of the true folds.

The images presented are based on a similar focus. It should be mentioned, however, that since OCT can be readily adapted to fibreoptic-based probes, other areas of traditionally poor visibility in light endoscopy, such as the anterior commissure, the subglottis and the laryngeal ventricle, could also be readily imaged using this technology.

In Figure 60.2, an OCT image of the laryngeal surface of an ovine (sheep) epiglottis and the associated histological section are shown. Several different layers of the epiglottic tissue are visible, with epithelium, lamina propria and cartilage being clearly demarcated. Glandular structures and vessels are also often visible.

Figure 60.3 presents an OCT image taken along the inferior portion of a porcine true fold, as evidenced by the transition from free-edge nonglandular mucosa to subglottal glandular mucosa observed in the OCT image and corresponding histological section. This image illustrates the ability of OCT to allow visualization of the epithelium, basement membrane and lamina propria of

© Hodder Arnold / Scott-Brown 7E

Figure 60.2 (a) OCT image of an ovine epiglottis; (b) corresponding haematoxylin and eosin histology section. Scale bars represent 150 μ m.

the true fold, as well as of certain structural features, such as glands and vessels. Note in particular that local epithelial thickness and transparency of the true fold can be readily deduced from these images, implying that OCT may prove useful for the diagnosis of hyperplasia, early-stage keratosis and papillomas, and other pathologies resulting in epithelial abnormalities not normally visible by conventional light endoscopy until an advanced stage. Since many laryngeal pathologies originate at the border between the mucosa and the epithelium, the ability to observe the integrity of the basement membrane via OCT imaging may have important implications for the use of this technology in aiding the diagnosis and monitoring of such laryngeal disorders, possibly including early stage carcinoma.

POLARIZATION-SENSITIVE OPTICAL COHERENCE TOMOGRAPHY

A monochromatic light wave carries three potential sources of information contained in the amplitude, phase and polarization state of its electrical field vector. Conventional OCT, by detecting only the intensity of the interference pattern resulting from interaction of the sample and reference optical beams, fails to quantify the effects of tissue on the polarization state of the sample light beam. An adjunct to conventional OCT, known as polarization-sensitive OCT, therefore has focussed on

© Hodder Arnold / Scott-Brown / ZE

Figure 60.3 (a) OCT image of the inferior surface of a porcine true fold; (b) corresponding haematoxylin and eosin histology section; (c) phase-contrast viewing of the stained histology section. Scale bars represent 150 μm .

exploiting the information contained in the polarization state of the light backreflected or backscattered from the sample relative to that of the reference beam to obtain information about the tissue microstructure.

In order to appreciate the power of PS-OCT and its potential applications, it is helpful to describe briefly the main mechanisms by which tissue alters the polarization state of light. Two mechanisms dominate the changes in the polarization state of light propagating through biological tissue: scattering and birefringence. Scattering changes the polarization of light mainly in a random manner, so it is generally not useful in mapping tissue structure. Organized linear structures, on the other hand, such as collagen fibre bundles with a clear orientation, can exhibit birefringence, resulting in a predictable change in polarization state. Many biological tissues exhibit birefringence, such as tendons, muscle, nerve,

bone, cartilage and teeth.¹⁴ Since changes in birefringence may, for instance, indicate changes in functionality, structure, or viability of tissues, PS-OCT images may contain information which can be used to evaluate tissue microstructure and health beyond the level possible with the use of OCT alone.¹⁵

The potential implications for clinical laryngology of the sensitivity of PS-OCT to organized linear structures, such as oriented collagen fibre bundles, are numerous. To illustrate, the human vocal fold lamina propria is generally subdivided into the superficial, intermediate and deep layers, with each layer having a characteristic composition and functionality. The relative thickness and integrity of these various layers appear to have a profound impact on voice. This idea is supported by the fact that the average adult will experience marked thinning of the superficial lamina propria relative to the intermediate and deep layers with increasing age,¹⁶ with a concomitant reduction in voice quality.

Histological studies of normal adult human vocal fold tissue have repeatedly noted increased density and longitudinal orientation of collagen fibres as one progresses from more superficial to deeper lamina propria layers.¹⁶ PS-OCT, due to its sensitivity to oriented collagen fibre bundles, may thus allow indirect detection of these lamina propria layers *in situ* and hence monitoring and possibly improving treatment of voice ageing. In the case of vocal fold scarring, the biomechanical integrity of the lamina propria is disrupted, resulting in reduced vocal fold pliability and thus decreased vocal range and quality. Scar tissue has collagen fibre orientation and density that is generally distinct from that of normal tissue and therefore PS-OCT may also prove useful in visualizing, localizing and treating vocal fold scars within the lamina propria. These capabilities could have a profound impact in the area of voice management.

Figure 60.4 compares a PS-OCT image of the inferior surface of a human true fold with the corresponding OCT image and histological section. Note the banding pattern apparent in the PS-OCT image of the vocal fold. A transition from white to black banding indicates a change in the polarization state of light. In particular, observe the marked increase in the thickness of the initial subepithelial white band in the leftmost portion of the PS-OCT image (corresponding to the true fold free edge) relative to that in the more subglottic tissue. The spatial location of this thickened initial band corresponds closely with the increased prominence of the superficial lamina propria in this region. Since collagen in normal superficial lamina propria is sparse and relatively randomly oriented, a net change in the polarization state of light will be slow to occur in this region. Hence, the thickness of the superficial lamina propria can potentially be inferred from the thickness of the initial subepithelial PS-OCT band. The true fold superficial lamina propria features critically in vocal health and disease. Although the presented results are not definitive, the potential of PS-OCT to detect

© Hodder Arnold / Scott-Brown, 7E

Figure 60.4 (a) Haematoxylin and eosin histology section of the inferior surface of a human true fold; (b) corresponding OCT image; (c) corresponding PS-OCT image. Scale bars represent 150 μm .

changes in the superficial lamina propria thickness and collagen alignment is an exciting area for future study.

Again, it must be stressed that further studies must be carried out to determine what the observed vocal fold polarization patterns truly indicate. In the case that these studies show, that the relative thickness and/or health of the lamina propria layers can indeed be indirectly assessed

by this imaging adjunct, PS-OCT could prove very useful to the study of lamina propria health and in the development of targeted scar treatment strategies.

SUMMARY

OCT and OCT adjuncts have enormous potential for improving the diagnosis, monitoring and both surgical and nonsurgical management of diseased ENT tissues. Conventional OCT provides objective information concerning the structure of tissue elements with distinct optical backscattering and backreflection properties. With regard to the larynx, conventional OCT studies of healthy laryngeal tissues *ex vivo* have demonstrated that OCT can detect spatial changes in the thickness and transparency of the epithelium, the content of the connective tissues in terms of glands and vessels as well as pronounced transitions in connective tissue type and the architecture of the basement membrane.¹⁷ PS-OCT holds promise for permitting indirect visualization of the layers of the true fold lamina propria, as well as of vocal fold scar beds. In addition, a number of other OCT adjuncts, such as spectroscopic OCT¹⁸ and phase dispersion tomography¹⁹ exist or are currently in development, each with distinct imaging advantages and capabilities over conventional OCT imaging. For ENT tissue visualization, the OCT imaging modality represents a rich and vibrant area of future research and discovery.

KEY POINTS

- The diagnosis and treatment of many ENT pathologies would benefit from the ability to image subepithelially and with high resolution *in situ*.
- Optical coherence tomography enables subepithelial imaging of tissue with a resolution ranging from 1 to 15 μm and is fibreoptically based, allowing OCT systems to be interfaced with a wide range of instruments, including catheters and endoscopes.
- With respect to laryngeal tissues, conventional OCT appears to be able to detect spatial changes in the thickness and transparency of the epithelium; the content of the connective tissue, including the presence of glands and vessels; and the integrity of the basement membrane.
- Polarization-sensitive OCT, with its sensitivity to organized linear structures, such as oriented collagen fibre bundles, may prove useful for vocal fold visualization and health assessment.

- OCT and OCT adjuncts hold substantial promise for improved diagnosis and treatment of many ENT disorders, a potential which remains largely untapped and constitutes an exciting avenue for future research, development and discovery.

Deficiencies in current knowledge and areas for future research

Although OCT and OCT adjuncts hold substantial promise for improved visualization of ENT-related tissues, OCT/OCT-adjunct feasibility studies for most of these tissues are either extremely limited or entirely lacking. For those ENT tissues that have been imaged with OCT, the primary focus of the imaging studies has been the necessary but insufficient first step of assessing the degree to which normal tissue microstructure can be accurately identified from OCT images. Before the OCT imaging modality can be regarded as a diagnostic tool in ENT, rigorous correlation of OCT/OCT-adjunct images of diseased tissue with parallel histology must be carried out to demonstrate that a given disease state can be accurately and reliably identified from OCT image structures. In the case of the larynx, although conventional OCT images of pathological laryngeal structures *in vivo* have been recorded,¹² the corresponding histology necessary to guide OCT image interpretation has most often been lacking. Thus, whether OCT/OCT-adjuncts can reproducibly and accurately identify laryngeal pathology or other ENT pathologies remains to be determined and constitutes an exciting and vital area of future work.

In addition to pathology identification, OCT or certain OCT adjuncts may prove useful in guiding laser and nonlaser-based microsurgery of ENT tissues. In laser microsurgery, PS-OCT may be particularly applicable, since laser damage of collagenous tissue has been shown to alter the tissue's effect on the polarization state of incoming light.²⁰ This is yet another exciting avenue for future research.

In brief, the following are a few of the many vital areas for current and future investigation:

- rigorous correlation of histology with OCT images of pathologic laryngeal specimens;
- further investigation of the potential use of PS-OCT in laryngology and correlation of PS-OCT images to laryngeal microstructure;
- investigation of other OCT adjuncts, such as spectroscopic OCT, to laryngeal imaging;
- further exploration of the possible applications of OCT/OCT adjuncts to ear-related imaging and a feasibility study of OCT applied to nasal tissue;
- exploration of the use of OCT or PS-OCT systems to ENT surgical guidance.

ACKNOWLEDGEMENTS

The authors thank Dr Steven Zeitels of the Massachusetts Eye and Ear Infirmary for fruitful discussions. We also thank Joe Seidel, PhD, for cutting and staining the histological sections appearing in this chapter, and Diane Jones of the Massachusetts Eye and Ear Infirmary for helping to procure human laryngeal autopsy specimens.

This work was funded in part by the Advisory Board Foundation, Eugene B Casey Foundation and the National Science Foundation Graduate Fellowships.

Contact endoscopy of the nasal cavity	764	research	767
Contact endoscopy of the nasopharynx	766	References	767
Oral cavity and oropharynx	767		

SEARCH STRATEGY AND EVIDENCE-BASE

The data in this chapter are supported by a Medline search using the key words contact endoscopy, *in vivo* diagnosis focusing on the clinical impact of contact endoscopy in the assessment and understanding of diseases of the upper aero digestive tract. The evidence level of contact endoscopic assessment is correlated with its learning curve involving knowledge of cytological, pathological and micro vascular patterns. It is difficult to classify the contact endoscopy findings by levels of evidence because we have direct access to the cell images in its more pure form. In some aspects the level of evidence is 1. However, in general, we would classify it as level 3 and 4 evidence.

INTRODUCTION

Contact endoscopy was first described by Desormeaux in 1865,^{1,2} who managed to obtain a direct view of the bladder mucosa. Interest in this technique then waned for almost a century, until technological advances had been made and Jaupitre³ began to promote it once more. More recently, Hamou^{4,5} developed and described his technique of microcolpohysteroscopy, in which contact endoscopy played a pivotal role. Its use in research to study the microvasculature of the larynx^{6,7,8,9,10} prompted further clinical applications within the upper airway. Contact endoscopy has now been employed to assess vocal cord pathology, the nasal mucosa, nasopharynx, oral cavity, oropharynx and the trachea.^{11,12,13,14,15,16,17,18,19,20,21,22}

Contact endoscopy allows *in vivo* and *in situ* observation of the mucosal blood vessels and superficial cells of the epithelium which have been previously stained with methylene blue. The experienced otolaryngologist is able

to perform a pathological evaluation during planned endoscopy and in many cases, an immediate diagnosis can be made. The information acquired does not render conventional biopsy and histological evaluation obsolete, rather it gives additional information to complement it. With contact endoscopy it is possible to detect microvascular changes and/or alterations in surface cellular structure that are suggestive of subclinical stages of disease. It is worth noting that because cells migrate towards the surface, most pathological processes can be seen by examining the superficial layers^{23,24,25} and it is precisely this that contact endoscopy addresses. The surgeon is able to assess the microscopic structure of the entire mucosa, allowing a more complete interpretation of the disease process. In other words, it offers the clinician a global perspective of the disease process with the facility of cellular and vascular mapping at any number of sites in the region. Furthermore, contact endoscopy has the advantage that it can be undertaken

with the patient awake in the outpatient setting or while anaesthetized in the theatre.

Contact endoscopy of the upper aerodigestive tract is still in its infancy. More and more centres are using this technique and its principles are being applied in other specialties as well. No doubt further technological advances will be forthcoming and the process will be refined. It is possible that in the future, contact endoscopy will occupy a central role in diagnosis, therapeutic planning and the follow-up of patients with a number of upper aerodigestive tract diseases. This chapter describes the current state of the art of contact endoscopy.

TECHNICAL DETAILS

Contact endoscopy can be undertaken in either the conscious or anaesthetized patient. Topical anaesthesia is all that is required. Several endoscopes have been developed and are commercially available but, for most purposes in the upper airway, only two endoscopes are required (7215 AA and 7215 BA, Karl Storz, Tuttlingen, Germany). With these endoscopes the clinician has direct access to the subsurface microvascular plexus and to the surface epithelium which can be viewed at a magnification of $\times 60$ and $\times 150$.

The mucosal surface to be examined is carefully cleaned by gentle suction or with a swab that has been moistened with saline. The surface is then stained with 1 percent methylene blue applied on a fragment of Spongostan®. The tip of the endoscope is placed gently against the surface of the mucosa allowing examination. Staining lasts for approximately four to five minutes at most sites before gradually disappearing. In the nasal cavity, the stain disappears more quickly as it is moved away towards the nasopharynx along the mucociliary pathway.

CONTACT ENDOSCOPY OF THE LARYNX

Contact endoscopy of the larynx and hypopharynx is performed under general anesthesia with conventional endotracheal intubation and synchronous microlaryngoscopy.

Normal appearance

Squamous cells at the vocal cord edge and in the hypopharynx have a polyhedral shape, being contiguous with each other. Their nuclei are round, darkly stained and the cytoplasm has a light blue tone. The nuclear:cytoplasmic ratio is regular and the overall morphologic pattern is homogeneous. Ciliated epithelium is present in most of the larynx. The nuclei of the cells are round, but the limits of the cytoplasm are difficult to define. Bundles

of cilia appear as filamentous structures that can be displaced by the tip of the contact endoscope. The transition from squamous to ciliated epithelium can be observed. Islands of squamous cells in the middle of ciliated epithelium may be seen and are not abnormal. The duct orifices of glands can also be identified. What is and what is not normal varies between patients and is very much influenced by such factors as age and diet and habits such as voice use and smoking.

Abnormal appearance

Metaplastic substitution of ciliated epithelium by squamous epithelium is most commonly seen in heavy smokers. It also occurs in patients with gastroesophageal reflux where the ciliated epithelium of the posterior commissure is replaced by squamous epithelium. It would seem that this interferes with normal mucus clearance.

When patients with chronic laryngitis are studied by this method, the epithelial pattern is found to be homogeneous, but epithelial cells have larger nuclei than normal and an increased nuclear:cytoplasmic ratio. As cell turnover is accelerated by inflammation, it is possible to visualize immature cells at the surface that are similar to those usually present in the intermediate layers of the normal epithelium. There are more blood vessels within the mucosa, but the vascular network keeps its normal pattern. In some cases of chronic laryngitis, filaments of fungal hyphae are identified and, if seen, should prompt treatment with antifungal agents.

Keratosis is detected very easily. Distinct and different stages of keratinization may be seen in the same patient. In the initial stages of keratinization, isolated cells without nuclei are observed. More advanced stages show groups of cells without nuclei, but with distinct cells still identifiable. With further progression of the disease it is not possible to distinguish the borders of individual cells and only large areas of an amorphous or laminar structure are visible.

In frank leukoplakia, degrees of cellular abnormality are identified that include heterogeneity of cell populations with nuclei of different colour, size and shape. The variation seen is in agreement with the histopathological concept of leukoplakia, in which different pathological alterations such as hyperkeratosis and dysplasia can develop simultaneously.²⁴

Contact endoscopy may not detect dysplasia when alterations are confined solely to the deep epithelial layers. However, in most cases, dysplasia is associated with involvement of the superficial layers as well and these are accessible to the endoscope. The most significant dysplastic changes^{23, 24, 25} are variations in nuclear size, shape and colour, together with changes of the nuclear:cytoplasmic ratio (dyskaryosis and anisokaryosis). The more pronounced the changes identified by contact endoscopy, the more severe the dysplasia. Vascular

changes also develop with dysplasia, where the normal vascular pattern is substituted by vessels of varying size. Unfortunately, when intense keratosis accompanies dysplasia it is not possible to observe the vessels beneath the surface.

In carcinoma, cell morphology is very variable with extreme heterogeneity of nuclear size, shape and staining characteristics. The nuclear:cytoplasmic ratio also changes from cell to cell. Nuclear inclusion bodies, prominent nucleoli and mitoses may be seen. The normal microvascular pattern and architecture is disturbed. Atypical vessels of different sizes and shapes are seen, as are thromboses, ectasias and rupture. In this situation, contact endoscopy enables the assessment of transitional zones between normal and abnormal mucosa and, as a result, a better evaluation of early stage disease. Surgeons also find it useful to guide biopsies and the collection of cytological samples so that safe margins may be identified. Interestingly, adjacent areas with normal squamous and ciliated cells often exhibit vascular changes (vascular loops) that signify an imminent change in status.

Contact endoscopy has also had an impact on the assessment and management of laryngeal papillomata. Typical vascular loops in the core of the papillomata can be seen as long as the associated keratosis is not too severe. In certain phases of the disease it is possible to identify koilocytes (ballooned cells) and inflammatory infiltrate. New lesions and incipient spread can also be detected. It would be hoped that eventually this information would translate into more accurate excision of papillomata and a reduced risk of residual or recurrent disease.

In summary, contact endoscopy helps the surgeon understand the pathophysiology of several common laryngeal conditions, such as metaplasia, caused by smoking, gastroesophageal reflux or vocal abuse, premalignant lesions, the early stages of laryngeal carcinoma, human papilloma virus (HPV) lesions and the association of cancer and HPV infection. In the future, tumour staging may well expand to encompass information on the cellular changes detected by contact endoscopy (Figure 61.1).

CONTACT ENDOSCOPY OF THE NASAL CAVITY

The anterior part of the nasal cavity may be examined easily with the patient awake using topical anaesthesia.

Normal appearance

As in the larynx, it is possible to evaluate the distribution and morphological appearance of the squamous and ciliated epithelia, glandular ostia, mucus and submucosal vascular networks. Squamous epithelium is usually present at the anterior tip and inferior border of the

inferior turbinate, the septum and nasal vestibule. This epithelium consists of polyhedral cells with dark blue nuclei and a light blue cytoplasm. Ciliated epithelium is present in most of the nasal cavity. The transition between ciliated and squamous epithelium is usually well defined, although in some cases isolated patches of squamous epithelium are seen in the middle of the ciliated epithelium.

The dynamic variation in volume of the turbinates caused by the nasal cycle explains the presence of small folds and papillae that tend to move in front of the endoscope. The duct orifices of glands are most prominent at the anterior end of the turbinates. Characteristically, they appear as concentric accumulations of cells with the innermost cell layers on a deeper plane. Dynamic changes in the glandular ostia are sometimes observed when manipulating the contact endoscope. The orifices of the glands become more noticeable when mucus is expelled. Mucus itself is seen as a moving layer that stains light blue and emanates from distinct papillae. It follows the contours of the papillae and carries away cell debris which either detaches spontaneously or as a result of the movement of the endoscope.

Characteristic features of the microvascular network have also been described. The papillae observed in the turbinates usually contain a small blood vessel. In the anterior part of the septum there are vessels of a very distinct calibre that are linked by anastomoses.

Abnormal appearance

Contact endoscopy in the nasal cavity is probably of most use in the study and management of chronic rhinosinusitis, allergic rhinitis, nasal polyposis and mucociliary diseases. In these conditions, it can be employed to assess the response to different types of treatment.²⁶

In patients with chronic rhinitis, squamous epithelium covers most of the inferior and middle turbinates and anterior septum. The nuclei of these cells look larger than normal. Areas of keratosis predominate in regions exposed to turbulent air flow, such as the anterior end of the inferior surface of the turbinates. Usually in these patients there is overproduction of mucus and the methylene blue stain clears very quickly. The density of mucous glands is increased and consequently more ostia are seen than in normal patients. Inflammatory cell infiltrates can be identified and differentiation of this infiltrate may help define the nature of the inflammatory process.

Mucus production is also increased in patients with allergic rhinitis. The papillae of glands are larger than normal and a U-shaped vascular axis is seen in the papillae. Ciliated epithelium is usually preserved in allergic rhinitis and there are fewer inflammatory changes than in the chronic nonallergic rhinitis group. In chronic nonallergic rhinitis, vascular congestion is diffuse and

Figure 61.1 Contact endoscopic assessment of a laryngeal tumour. (a) Laryngeal tumour ($T_3 N_2 M_x$); (b–h) Contact endoscopy ($\times 60$). (b) Right arytenoid region: normal squamous epithelium. Note the regular appearance of the cells and their nuclei. (c) Left arytenoid region: tumour present. The nuclei of the epithelium are irregular in size and shape. Numerous mitoses are visible. (d) Right vocal cord: malignant changes are easily visible, as well as variations in nuclear size and shape. (e) Left vocal cord: tumour pattern. (f) Right false cord: transition from normal epithelium to tumour pattern.

independent of the papillae. Very enlarged vessels are sometimes identified.

Examination of nasal polyps has shown that the anterior face is covered by squamous epithelium while the

rest of the polyp is covered with ciliated cells. Metaplastic changes may be present and are related to the duration of exposure to turbulent air flow. Nasal polyposis is usually accompanied by inflammatory cell infiltrates.

Figure 61.1 Contact endoscopic assessment of a laryngeal tumour. (Continued) (g) Right false cord: islands of atypical cells. (h) Medial aspect of the right arytenoid: tumour pattern associated with presence of koilocytes. (i) Contact endoscopy ($\times 150$), koilocytes (ballooned cells), medial aspect of the right arytenoid. (j) Contact endoscopy ($60\times$), vascular loops typical of HPV, right arytenoid region.

Contact endoscopy can, and perhaps should, be used during functional endoscopic sinus surgery to assess the state of the mucosa. The type and degree of abnormalities can help the surgeon decide which areas of mucosa to remove and which to retain.

CONTACT ENDOSCOPY OF THE NASOPHARYNX

Contact endoscopy of the nasopharynx can be performed through the nose under local anaesthesia. Its main use is in the long-term follow-up of patients who have been treated for nasopharyngeal carcinoma.

Normal appearance

Although the majority of the nasopharynx is lined with ciliated epithelium, it is usual to see areas of squamous epithelium, typically in the central and inferior part of the

posterior wall. Orifices of glandular ducts are present throughout the nose.

Abnormal appearance

An irregular vascular pattern is seen in areas with nasopharyngeal carcinoma. Atypical vessels, ectasias, thrombosis, blood cell aggregates and increased vascular fragility are common. The tissue is extremely fragile and will bleed easily if probed too firmly with the endoscope. As with all malignancy, the stained epithelium of the nasopharynx shows anisokaryosis, heterochromasia and hyperchromasia. There are often clusters of malignant cells with hyperchromatic nuclei. Most nuclei are irregular in shape, others fusiform in shape (fibroblast-like) and some are large and oval. Occasionally, it is possible to observe the nucleolus, nuclear inclusions and even mitoses. There is almost always a marked lymphocytic infiltrate. The transitional zone between the tumour

and normal tissues is very important and it is usual to see inflammatory infiltrates and/or keratosis. Small islands of malignant cells are sometimes found in the middle of the apparently normal ciliated epithelium in areas immediately adjacent to the tumour.

It is worth emphasizing that a number of centres regularly use contact endoscopy for both the diagnosis and follow-up of their patients with nasopharyngeal tumours.^{27, 28} In particular, this technique is used in areas where nasopharyngeal carcinoma is endemic as an office-based procedure to confirm the diagnosis, identify submucosal disease when malignancy is not detected endoscopically and to identify persistent and recurrent nasopharyngeal carcinoma. Contact endoscopy is also used to select areas for biopsy.

ORAL CAVITY AND OROPHARYNX

Contact endoscopy of the oral cavity and oropharynx is performed either with or without topical local anaesthesia.

Normal appearance

It is important to remember that the morphology of the oral mucosa varies from site to site. In some parts it is keratinized, the so-called masticatory mucosa, while in others it is not, as in the lining of the mucosa or specialized mucosa. These different patterns must be recognized if pathological changes are to be understood and interpreted.

The transition from the keratinized epithelium of the lip to the nonkeratinized epithelium of the vestibule is seen easily. The greater part of the mucosa of the lip, the alveoli, cheek, floor of the mouth, ventral surface of the tongue and soft palate is also nonkeratinized squamous epithelium. Some keratinization is to be expected in the cheek opposite the occlusal plane. The masticatory mucosa covering the hard palate and gingiva is a keratinized epithelium. On the dorsum of the tongue, filiform and fungiform papillae can be seen. Contact endoscopy in the oral cavity and oropharynx has great potential in areas such as the diagnosis of early cancer, the study of tumour margins, the assessment of the response to radiotherapy and chemotherapy and to identify subclinical stages of disease.

SUMMARY

Contact endoscopy allows *in vivo* and *in situ* assessment of the mucosa and underlying microvascular network. With experience, the operator can distinguish between normal and abnormal tissues. It represents a new phase in the development of endoscopy. This technique can

improve the accuracy of diagnosis and give useful information about the extent of disease. It helps identify earlier subclinical stages of disease than was previously possible.

Many centres use this technique and global experience is increasing.^{27, 28, 29, 30, 31, 32} The accuracy and clinical applicability of contact endoscopes will continue to be enhanced by improvements in optical systems, new cell dyes, markers, fluorescent products,²² light sources, image processing and better recording techniques.

KEY POINTS

- Contact endoscopy is a simple, noninvasive technique that offers real-time information about disease processes.
- Contact endoscopy allows the mapping of an entire mucosal surface in the conscious or anaesthetized patient.
- Contact endoscopy may eventually be used to monitor changes that develop in the premalignant stages of the disease.

Deficiencies in current knowledge and areas for future research

- Contact endoscopy has great potential for the early diagnosis of nasopharyngeal cancer. However, more experience needs to be gained to define its role as a screening procedure.
- More knowledge is needed on the pathogenesis of squamous metaplasia and atypical hyperplasia.
- Articulation of contact endoscopy with other technologies such as fluorescence, confocal and narrow band imaging will further enhance the accuracy of *in vivo* and *in situ* diagnosis.

INTRODUCTION

Caring for children has been an integral part of otolaryngological practice since the specialty began. Textbooks of paediatric otolaryngology have a shorter history. Although Douglas Guthrie published a small booklet *Diseases of the ear, nose and throat in childhood* in 1921,¹ Wilson's 1955 *Diseases of the ear, nose and throat in children* was the first substantial English-language text devoted to paediatric otorhinolaryngological disorders.² This important little book provides early descriptions of aminoglycoside-induced deafness, the technique of tracheobronchoscopy in children and obstructive sleep apnoea, then known as 'aproxexia'. It is a measure of the maturity of paediatric otolaryngology as a discrete subspecialty, and a recognition that the pathophysiology, management and expectations from treatment of diseases in children are often very different from what obtains in adults² that this is now the third edition of *Scott-Brown's Otorhinolaryngology, Head and neck surgery* which includes a separate section covering paediatric aspects of our specialty.

HISTORY

Mastoid surgery for the treatment of otological sepsis was popularized by Sir William Wilde (1815–1878) who described what we now know as otitis media with effusion – 'strumous otitis'.³ Wilde recognized the association between 'strumous otitis' and Eustachian tubal dysfunction, described tympanocentesis as a treatment and popularized the use of a myringotomy knife which is not dissimilar to that used today.⁴

The Victorian and Edwardian laryngologists, notably Morrel McKenzie and Sir Felix Semon in London, had large paediatric practices and dealt with often-fatal upper respiratory tract pathologies, such as diphtheria. McKenzie provides us with the first description of laryngeal papillomatosis. He noted the post-mortem findings in a child who died of airway obstruction in what he poignantly described as a 'home for the friendless'.⁵

In Europe, Gustav Killian pioneered suspension laryngoscopy and tracheobronchoscopy in Freiburg, Bresgau at the beginning of the twentieth century. The principles were soon extended to children. Chevalier

Jackson (**Figure 62.1**) in Philadelphia established a reputation throughout the United States for the skill with which he could extract bronchial foreign bodies. A brilliant teacher, he illustrated his work in his own hand and was probably the single most important figure to popularize airway endoscopy in children on both sides of the Atlantic. The pioneering work of British physicist Harold Hopkins in the design of modern ‘rod-lens’ telescopes (**Figure 62.2**) moved paediatric airway surgery to new levels.

Modern-day paediatric otolaryngologists are acutely aware of the debt they owe to paediatricians and anaesthesiologists. Sophisticated diagnostic and therapeutic procedures in children are only possible because of the huge advances made in improving the survival and care of small babies.

It is difficult for those of us trained in recent times to appreciate just how harrowing airway disorders in children could become before the equipment and skills which we now take for granted were developed. Joseph O’Dwyer (New York) is credited with the first successful emergency endotracheal intubation in a child. In 1886 he presented 50 cases with a 70 percent mortality. The technique remained controversial but was enthusiastically taken up by a Chicago physician, Dr Frank Waxham, who used it to provide an alternative airway for children with diphtheria.⁶ Long-term nasal endotracheal intubation as an alternative to tracheotomy was popularized only from the 1960s onwards. In 1955, Wilson wrote of emergency tracheotomy in children, ‘these are desperate cases at best, and it may be a comfort to remember that the worst thing which can happen is that the patient will die. This is unfortunately a likely event in any case.’²

The late Sylvan Stool, a pioneer American paediatric otolaryngologist and historian recounts his earliest experiences with the removal of bronchial foreign bodies: ‘The telescopes and cameras of today make endoscopy easy. Anybody can remove a foreign body and look like a technical master. You should have been around when we were changing that little bulb on the end of the Jackson bronchoscope three or four times during a case.’⁶

Figure 62.2 A modern ventilating bronchoscope incorporating a ‘Hopkins rod’ telescope.

Airway endoscopy in children is now a highly skilled – and safe – undertaking. This is due to parallel advances in equipment and the training of personnel – otolaryngologists, anaesthesiologists and support staff. The equipment required for this work is now considerable (see Chapter 86, Stridor).

The first paediatric ENT ward was opened in Poland in 1895. This was at the Children’s Hospital in Warsaw under the supervision of Dr Jan Gabriel Danielewicz. An independent children’s ENT department was established in Budapest immediately after the Second World War. In Italy, Dr Carlo Mancini headed a department in Brezia in 1950. Children’s ENT services were quickly established in Czechoslovakia, Slovakia, and Bucharest. In Britain ENT departments were founded in the early part of the twentieth century in the children’s hospitals at Great Ormond Street London, Alder Hey Liverpool and in Bristol.

Advances in diagnosis and rehabilitation have greatly improved outcomes and expectations for the deaf child. Although audiological medicine has developed as a separate specialty, and a multiplicity of professionals

work in tandem to care for children with hearing loss, this remains a core part of the workload of otolaryngologists who look after children. Hence, much of the foregoing section is devoted to this topic.

SOCIETIES

As new specialties emerge, the societies and associations which promote their aims and allow colleagues to share views, advances and collective wisdom develop. Loose gatherings of otolaryngologists with an interest in children were formed in Eastern Europe from the beginning of the twentieth century. In the United States the Society for Ear Nose and Throat Advances in Children (SENTAC) met in 1977. The American Society for Pediatric Otolaryngology (ASPO) (www.aspo.us) was founded in 1985. The European Working Group in Pediatric ENT was founded in 1977 and later became the European Society for Pediatric Otolaryngology (ESPO) – a forum for discussion and advances in paediatric ORL through international meetings and via its journal the *International Journal of Pediatric Otolaryngology*.

In Britain it was not until 1991 that the British Association for Paediatric Otolaryngology (BAPO) (www.bapo.org/uk) was formed. The idea for a British society came about at a meeting of colleagues attending the international congress at Ghent in 1990. Surviving mementos include a signed menu (**Figures 62.3 and 62.4**) from the Chez Armand restaurant (John Graham FRCS, personal communication).

THE SCOPE OF PAEDIATRIC PRACTICE

Almost all otolaryngologists look after children. For most this represents a vital and rewarding part of their clinical workload. The spectrum of diseases ranges from common problems such as adenotonsillar hypertrophy,

© Hodder Arnold / Scott-Brown 7E

Figure 62.4 The BAPO logo.

rhinosinusitis and otitis media to more esoteric and challenging presentations such as subglottic stenosis, tumours of the salivary glands and congenital deformities of the ear. A general otolaryngologist or an otolaryngologist with a broad-based practice but an interest in children can satisfactorily look after most children. Those with complex or rare conditions, the very young and those with multiple medical pathologies requiring the attention of paediatricians, neonatologists and intensivists are best managed in a designated children's centre in close liaison with other professionals. Hence the skills of 'paediatric otolaryngologists' are increasingly required at these centres.

PAEDIATRIC OTOLARYNGOLOGISTS

Paediatric otolaryngologists look after 'special problems, in special children in a special institution'.⁷ Needless to say, they will have had training that reflects this remit.

Special problems

The 'special problems' that paediatric otolaryngologists look after include congenital and acquired airway disease and the otorhinolaryngology (ORL) pathologies which occur in children who require management on a special care baby unit (SCBU) or in the paediatric intensive care unit (PICU). Much of this work is diagnostic and supportive. It lacks the glamour and appeal of laryngo-tracheal reconstructions, cricotracheal resections, etc., which are procedures now rarely done outside of highly specialized units. Day-to-day paediatric ORL involves liaison with paediatricians, paediatric anaesthesiologists, intensivists, nursing and allied staff and, most of all, often distraught parents and carers. The work is by its nature unpredictable and often occurs 'out of hours'. The required skills are not just technical but relate to the judgement and experience needed to make decisions on small and often very ill babies and to contribute to a multidisciplinary team.

Special children

All children are special but some of the children with whom a paediatric otolaryngologist deals are very special indeed because of their complex medical needs. These include syndromic children, children with genetic diseases, children with often severe locomotor and neurological dysfunction, and children with communication difficulties and learning disabilities, which range from mild to profound. All have parents/carers who are intimately and uniquely involved in the child's health care decisions and who simply cannot be appropriately looked after in a general ENT clinic setting. These children get the range of ORL problems with which we are all familiar, for example adenotonsillar disease, rhinitis, otitis media, often against a background of severe multisystem disease. They need a completely different management approach to that needed for otherwise healthy children. They are best looked after by clinicians with skills that can only be developed by working with such children and parents and who have an appreciation of the natural history of diseases in such settings. If they require surgery it is often wholly inappropriate that this should take place outside of a specialist children's centre where facilities for anaesthesia, recovery and postoperative intensive care are available as required. Special needs children also develop unique problems such as sialorrhoea, obstructive sleep apnoea

and aspiration which are best managed by experienced personnel in a designated setting.

Special hospitals

Children's hospitals or 'centres' are 'special' places not because of their geographic location but because of the availability of skilled personnel in a unique multidisciplinary setting. Support services such as anaesthesia, speech and language therapy, paediatric imaging, children's specialist nurses, feeding clinics, regional facilities such as craniofacial surgery and neonatal surgery are simply not found outside these centres. 'Centres' include not only the specialist children's hospitals but also paediatric facilities in the few large teaching hospitals where supraregional services for children are concentrated. Perhaps the defining features of such a centre are the availability of a dedicated paediatric surgical team and the presence of a designated PICU. A paediatric otolaryngologist will have the major proportion of his/her clinical commitments at such a centre.

DEVELOPING ENT SERVICES FOR CHILDREN

It is essential that otolaryngologists are to the fore in local discussions on service planning that have an impact on children – and that is most discussions in the sphere of health care. Up to 30–50 percent of our workload involves the care of children.⁸ Otolaryngologists have, and must maintain, an important role as strong advocates for children.^{9, 10}

Otherwise healthy children with common pathologies where anaesthetic risks are minimal are best looked after near their homes in settings that are convenient for parents and carers. Provided support services are adequate there is no merit in relocating all this work to already overstretched children's centres.

Children with airway obstruction who can be cared for locally – for example those with acute infections, croup, the older child with sleep apnoea – are appropriately managed by a designated otolaryngologist with a special paediatric interest.

Increasingly, one or more members of a team of otolaryngologists will assume a lead role in looking after such children and may also lead the development and management of audiology services for children, given the shortage of audiology professionals.

THE GENERAL/SPECIALIST OTOLARYNGOLOGIST

What of the general ENT surgeon or the otolaryngologist with a special interest in, say head and neck disease, skull base surgery or rhinology? Can he/she continue to include

children in his/her clinical practice? Emphatically yes. It is essential that the skills of these surgeons are made available as needed for often rare and complex problems in children. Special local arrangements may also be needed for cochlear implantation where otologists with a largely adult practice may be best placed to establish a service with a mixed adult and children base. Rhinologists with an adult base may be best to deal on an ad hoc basis with some of the complex nasal problems that occur in children.

Head and neck problems in children are very different to the range of disease seen in adults. There is much to be said for developing the expertise of a very small number of otolaryngologists who take a particular interest in these challenging cases rather than regarding them as within the ambit of all adult head and neck oncologists.

TRAINING THE OTOLARYNGOLOGISTS OF THE FUTURE

The fortunes of paediatric otolaryngology are very much in the ascendancy. The specialty is particularly popular with trainees, assuring us a bright future. Training programmes in ORL must include sufficient exposure to the diagnosis and management of ENT disease in children to enable otolaryngologists to continue with a broad-based practice that includes the management of children. The specialist paediatric otolaryngologists of the future will need more advanced training. Fellowship programmes are well established in the United States and represent a model that could usefully be adopted elsewhere. Otolaryngologists – paediatric or not – need to act as feisty advocates for children. It is easy for paediatric aspects of services to be marginalized and for children to be disadvantaged, particularly when ENT services or training programmes are reconfigured. Continued vigilance is essential.

KEY POINTS

- Paediatric otolaryngology is as old as the specialty of otolaryngology itself.
- Looking after children is an integral part of the work of an ENT specialist.
- The pathophysiology and natural history of disease may be very different in children.
- Some children will require the specialist knowledge and skill of a paediatric otolaryngologist.
- Training in the generic skills required to care for children is essential to ORL practice.

Deficiencies in current knowledge and areas for future research

- There is an increasing trend to centralize children's surgery. Otolaryngologists must ensure they are to the fore in local service planning.
- There is a need for careful workforce planning and the establishment of fellowship training programmes to maintain the advances we have made.

ACKNOWLEDGEMENTS

SEARCH STRATEGY

This chapter was compiled largely from the authors' personal experience as clinicians and teachers, supplemented by their personal bibliographies. The websites of the Departments of Health (www.doh.gov.uk) and Education and Skills (www.dfes.gov.uk) were consulted for the sections on consent, for information on the National Service Framework for Children and for 'Every Child Matters'.

INTRODUCTION

Major recent developments in UK government policies that relate to children have been informed by the findings of the Kennedy¹ and Laming² inquiries. Their recommendations, together with those of subsequent government publications (the *National service framework for children* and *Every child matters*) provide a comprehensive blueprint for best practice in children's services and are universally applicable. While many of their recommendations have been routinely practised for a long time, they are a useful reference source and what follows is in keeping with their spirit.^{3, 4}

Children and parents often remember vividly their first encounter with a 'specialist'. For many, it will be the child's first contact with doctors/clinics and hospitals. It is worthwhile investing time and effort into making the experience as pleasant and productive as possible. The principles that make for a satisfactory and productive visit to the otorhinolaryngology (ORL) clinic apply to both adults and children, but some features of the paediatric consultation are unique.

The decision to seek advice will have been made not by the patient but by the child's parent(s) or carer. With infants and young children the history and a discussion concerning diagnosis and management is by proxy, i.e. involving the parent/carer (usually the mother) rather than the child. Often the mother will be anxious, perplexed and 'worried if she is doing the right thing'. While the primary purpose of the visit is for the doctor to make a diagnosis and advise on an investigative/treatment plan, a good consultation is far more than that. It represents an opportunity to establish a rapport with the parent and child that in some cases may last for much of the patient's childhood. It is the forum for explaining, in simple and understandable terms, what the doctor's opinion is on the child's condition and for discussion of treatment options. It provides the chance to familiarize the mother and child with the hospital/clinic, to introduce them to other members of staff who may be involved in the child's care and to reassure them that the child will be well looked after should they need to come into hospital.

Most hospitals demand that a trained children's nurse be available for all paediatric consultations. Specialist

nurses who work in paediatric ORL are invaluable. Staff numbers need to be sufficient not only to support the working of the clinic, but also to ensure the safe supervision of patients and their siblings while parents are preoccupied. Thus paediatric clinics need more nurse input than general ENT clinics.

REQUIREMENTS FOR THE CLINIC

The waiting area

A paradox of planning hospitals and clinics for children is that despite children's small size their requirements for space are much greater than those of adults. In an ideal world, children would only be seen in dedicated clinics designed with their unique requirements in mind but this is not always possible. Whatever the setting, seating has to be comfortable and suitable for all ages. Wheelchair access is essential as are facilities for breastfeeding and for changing of babies' clothes. Children become bored and fractious if they wait too long. As well as organizing clinic appointments to minimize waiting, a well-equipped waiting area with toys, paper, coloured pencils and computer games will help to keep children occupied and reduce parental stress. Play therapists greatly enhance the quality of a child's hospital visit. Some progressive hospitals employ clowns and entertainers. Adolescents may feel uncomfortable surrounded by hordes of small children and need to have their particular needs catered for as well. Some hospitals have separate clinics for adolescents scheduled for after school times and they usually appreciate a separate ward or section of a ward if they require inpatient care.

'Special' clinics

There is much to be said for running separate clinics for some categories of patients. These may include 'special needs' clinics and clinics where multidisciplinary input is required, for example audiology, cleft palate, etc. Thought needs to be given to the organization of time and space in such clinics because a balance needs to be struck between making the most efficient use of time by all concerned and the need not to overtire or overwhelm the child by seeing too many adults in one room at one time.

The clinic rooms

An examining room should be able to accommodate not just the patient, doctor and nurse but two parents, one or more siblings, sometimes in 'Moses baskets' or push-chairs, and often a grandparent. In the case of special needs children, there may be a need to accommodate a wheelchair, oxygen cylinders and the various bits and

pieces the mother needs for tracheotomy care and gastrostomy management. Ideally, the examining room should have a small play area as well where the child and siblings can occupy themselves while the mother gives the history and the doctor can quietly observe the child. Instruments other than those in frequent use should be discreetly put away. Small children will be frightened at the sight of an array of picks and hooks. Facilities for hand washing are essential. An operating microscope is essential, either in the room or nearby. Endoscopy – both flexible and rigid – is now so frequently performed in an outpatient setting in children that it can be regarded as a mandatory requirement in a paediatric clinic. A suitable range of scopes with facilities for safe storage and ideally a monitor and image capture system should be available, not just for specialized airway or voice clinics but as a routine requirement for any paediatric consultation. The physical environment must be safe for the child, with no spirit lamps, sharp instruments or corners.

PREPARATION FOR THE CONSULTATION

A hospital visit is a routine event in the life of the doctor, but a major event for the mother and child. Arrangements may have been made for sibling childcare, the mother will have had to discuss the visit with the child's teacher and often one or both parents will have taken a day off work. Parents or children must never feel rushed. If you need to hurry them along, the clinic has not been properly planned. It makes for a smoother consultation if the doctor has taken the trouble to read the case notes and learn the child's name before the consultation starts. If the child has a syndrome or an unusual medical condition read up about it in advance. Make sure you have checked any investigations the child may have had, including hearing tests. As far as possible, children and parents appreciate continuity and like to be able to see the same doctor on successive visits. It is not the authors' place to advise on dress code, suffice to say that your best tailored suit and crisp, cotton dress shirt will neither impress the average eight year old or continue to look crisp at the end of a busy morning!

THE CONSULTATION

Welcome the child and carer(s), make eye contact and start by introducing yourself. Introductions should include others in the room and include permission for medical/nursing students to be present and for them to examine the child. Multidisciplinary clinics can be particularly intimidating as by their very nature several specialists are present. It is good practice for all to wear a name badge and many hospitals will demand this. This does not excuse the need to introduce yourself and other members of the team. Learn and use the child's name.

Establish who is with the child and if not the parents note names, for example of foster carers or grandparents. A well-conducted consultation where the mother/carer feels she has been listened to and had the child's symptoms properly and simply explained is an important part of the management of many childhood ailments. Many doctors regard themselves as excellent communicators because of their capacity to talk well. Fewer listen well! Listen, watch the child, look at the mother's facial expressions, pick up as many nuances as you can to help you in your decision making and to improve your rapport with mother and child. Resist the temptation to conduct the entire consultation without involving the child directly in the discussion. Listen and respond to both the child and the family and encourage the child to give her own views. Good consultation skills can be taught, learned and improved upon. Parents may be angry, upset, uncooperative, seeming not to listen, evasive or challenging in a variety of other ways, but it goes without saying that as the child's doctor you must never become short-tempered no matter how difficult the exchange or how great you feel the provocation is.

If interpreters are needed, it is best to make arrangements in advance. Pay attention to the seating plan, especially with signing interpreters. Professional interpreters are preferable to relatives and friends, and using elder siblings to interpret is undesirable. Speak slowly and clearly to the patient's mother at normal volume and use plain English without jargon or colloquial terms.⁵

The history

Doctors are taught to take a history in a structured didactic way. This is not always suited to paediatric work. It is best to start with an open question, such as 'what are your worries about Jennifer?' and let the mother explain in her own words, without interruption until she feels she has got her message across. More direct questions can then be put. Always ask about the impact of symptoms on the child herself and on family life. If parents volunteer to show you the child's 'health book' or growth charts, make sure you look at these even if you feel they are not directly relevant. Parents understandably feel any record of their child's health and progress must be important.

The examination

Most children are happy to be examined (**Figure 63.1**). An astute clinician will have commenced the process as soon as the child enters the room. Stridor, mouth breathing, syndromic features and the child's general alertness may give clues. Smaller children are best examined sitting on the mother's knee. Tell the child in an age-appropriate way what you are going to do at all stages of the examination – do not assume they have been listening and expect it. Children do not need to be

© Hodder Arnold / Scott-Brown 7E

Figure 63.1 Examining a young child.

restrained for clinical examination and if the child is not cooperative it is best not to press or coerce them. When potentially uncomfortable procedures such as the removal of wax or foreign bodies are to be performed, it is important to be truthful and not to tell the child it will not hurt if it may do. If you do hurt the child explain and, where appropriate, apologise.

Otoscopy

Most children will tolerate the gentle introduction of an electric auriscope. Some units use video-otoscopy which has the advantage of enabling the mother and child to see an image of the eardrum on a monitor and also permits pictorial record keeping.

The nose

Children do not like the Thudicum's speculum. A good view of the nasal cavities can be obtained by elevating the tip of the nose or by using an otoscope with a large speculum (**Figures 63.2** and **63.3**). Rigid endoscopy may be tolerated by the very young, where a fine-calibre telescope will be needed, and in older children who will cooperate if the procedure is explained to them. Local anaesthetic sprays often make matters worse and if a child finds the procedure uncomfortable it is best to just abandon it.

The nasal airway can be assessed by gently occluding one nostril at a time and asking the child to breathe gently. The spatula test in which a cold tongue depressor is placed under the nostrils and the condensation pattern inspected to determine whether there is occlusion of the nasal airway is especially helpful in very young children (**Figure 63.4**).

The pharynx and larynx

Try to obtain a view without using a tongue depressor. Many young children will tolerate mirror examination of

© Hodder Arnold / Scott-Brown 7E

Figure 63.2 Anterior rhinoscopy.

© Hodder Arnold / Scott-Brown 7E

Figure 63.3 Using an aural speculum for nasal examination.

the post-nasal space, but flexible endoscopy is increasingly used and often well tolerated. The adenoids, hypopharynx and larynx can be seen in this way. The function of the velopharyngeal sphincter can also be assessed and recorded.

Some children will tolerate mirror examination but often the view is unsatisfactory and, if the child will permit examination via the mouth a 70° rod lens telescope is very useful as its slim shaft fits easily between large tonsils.

The neck

It is important to inspect and palpate the neck, but remember that enlarged lymph nodes in children are so common as to be normal. Other swellings in the neck include cystic hygroma, thyroglossal cysts and salivary gland swellings. These are dealt with in Chapter 99,

© Hodder Arnold / Scott-Brown 7E

Figure 63.4 The spatula test.

Branchial arch fistulae, thyroglossal duct anomalies and lymphangioma and Chapter 97, Salivary gland disorders in childhood.

Investigations

Other than audiometry and tympanometry, few investigations are needed for the common presentations at a children's ENT clinic. Hearing tests are considered in Chapter 68, Hearing tests in children.

Management plan

The parents have come to see you to hear your opinion on their child's condition and to discuss a management plan with you. This part of the consultation is vital and must never be rushed. Explanations should be straightforward and easy to understand, involving the child where appropriate. Models, diagrams, printed and audiovisual material can aid this process greatly. For many interventions, such as tonsillectomy, adenoidectomy and insertion of tympanostomy tubes, there will be more than one management option and it is important that these are

discussed in an open and honest way. This sometimes means doctors have to admit doubts and uncertainties which are best explained without embarrassment so that a way forward can be agreed by consensus. The treatment will be a matter for negotiation between the otolaryngologist and the mother and/or child and questions should be encouraged. Some parents see the ORL consultation as a means to confirm a treatment option they have already decided on with their family doctor, for example tonsillectomy for recurrent sore throats. Others are reluctant to consider any surgery, but all will greatly appreciate an informed discussion and an honest presentation of the evidence for current practice focused on the specific needs of their child. In general, parents appreciate a discussion with the senior clinician, but this needs to be balanced with the need for residents and juniors to see patients and improve their diagnostic and consultation skills.

Functional problems

Problems for which no organic cause can be found are encountered in paediatric ENT practice, particularly in adolescents. They often take the form of unexplained coughs, pains or abnormal hearing tests. It is important to investigate for underlying organic pathology. Where none is found, the patient should not be led to feel that the clinician believes that the problem is entirely imaginary because this breaks down confidence. An approach in which the problem is treated as a disorder of body function rather than mental function is more likely to be helpful.

Breaking bad news

If bad news has to be given, such as a diagnosis of deafness, the need for long-term tracheotomy or suspicion of malignancy, the help of a senior clinician should be sought immediately. Parents and children remember such episodes with chilling clarity – often for a lifetime. Great harm can be done by insensitive or even well-meaning but inexperienced handling of such situations. Many hospitals have policies on the breaking of bad news. In the clinical situation, it is not always possible to follow these blueprints to the letter, but every consideration should be shown to the family. The setting in which the news is to be broken should be considered beforehand and appropriate supporting staff briefed. The consultation must not be rushed. Parents will often be shell-shocked by unexpected bad news and may not remember detailed information. Further discussion should be offered if needed and it is helpful to make a clear management plan beforehand, so that there is no uncertainty about the next steps to be taken or the timing of the next appointment.⁶

Prescribing for children

In general, otolaryngologists do not prescribe a large range of drugs in the outpatient setting. Where drugs are prescribed, it is essential to be aware of the correct dosage and presentation for children and that the child's mother understands how to give the medication. Evidence-based prescribing is not always possible for children, and where unlicensed and off-label medicines are used, local safety standards should be adhered to.

Recording and communication of the outcome of the consultation

Hand-written notes should be legible, signed, dated and clearly identify the writer. Subject to the need for confidentiality, there is often a need to inform more people of the outcome of the consultation in paediatric work than there is with adults (e.g. educators, community paediatricians, geneticists, etc.). Parents should be made aware of this and correspondence should be copied to all appropriate parties including the parents/carers themselves.

Child protection issues

All professionals involved in paediatric work need to be aware of the potential for children to be subject to abuse or neglect. Of those children subject to physical abuse some 75 percent suffer injuries to the head and neck.^{7,8} Examples of presentations that may arouse suspicion include auricular haematomas, traumatic perforations of the eardrum, nasal injuries, pharyngeal lacerations, dental trauma and tears of the lingual frenulum. Children are naturally active and some of these injuries occur in the rough and tumble of normal childhood but if there is a pattern of injury or if the presentation seems inappropriate clinicians have not only an ethical but a legal duty to raise concern. Needless to say, such concerns must be handled with great sensitivity, but prompt action should be taken and comprehensive notes, detailing the injuries and the reasons for suspicion, should be made. All hospitals which look after children should have an agreed mechanism for dealing with such concerns, usually involving the help of a senior and experienced paediatrician.² Clinicians who have little direct experience of child protection will need the advice and support of a more experienced colleague.

CONSENT IN CHILDREN

Competence

It is axiomatic that any interventions proposed in children require consent. While the law has primacy this will vary according to the administration or health service

that one is working in and it is imperative that doctors who care for children are thoroughly conversant with the law relating to consent and parental responsibility. Whatever the legal requirements it is important to respect the legitimate concerns of parents, be they mothers, fathers, single, married or divorced, to be cognisant of cultural and individual family dynamics and to proceed by consensus wherever possible. What is unique about consent in paediatric practice is that young children will not have the understanding required to give informed consent, although it is good practice at all times to involve the child as much as possible in decision making.

The following is based on English law and on custom and practice in the UK.

Once children have reached the age of 16 years they are deemed to be competent and can therefore give consent themselves. Nevertheless, it is wise to encourage teenagers to involve their families in decision making. 'Competence' implies the capacity to comprehend and retain information material to a decision, and the ability to weigh this information in decision making. Some 16- and 17-year-olds may not be competent by reason of unconsciousness, pain or severe learning disability. In such cases, a person with parental responsibility may take a decision for the child, but over the age of 18 nobody can give consent for another person, and if such a person is not competent clinicians may have to take decisions without consent that are in the best interests of the individual.

Some children under the age of 16 will be able to understand what an intervention involves. The courts have determined that such children are competent if they have 'sufficient understanding and intelligence to enable him or her to understand fully what is proposed'.⁹ This is colloquially known as 'Gillick competence'. The determination as to whether the child has Gillick competence rests with the clinician.¹⁰

Parental responsibility

If a child is not competent, only a person exercising parental responsibility can give valid consent for that child. This is usually one or both of the child's parents. In England and Wales 'parental responsibility' is as defined by the Children's Act 1989 and amended by the Adoption and Children Act 2002. The child's natural mother has parental responsibility as has the father if he is married to the mother or was married to the mother at the time of the child's birth. Unmarried fathers may acquire parental responsibility by order of a court or by a 'parental responsibility agreement'. For births registered after December 2003, a father named on the birth certificate has parental responsibility irrespective of his marital status. Grandparents and others who look after children cannot give consent unless special legal arrangements have been made. Consent is only legally required from one parent, but where applicable it is good practice to

ensure that both parents and the child are involved in the decision-making process.

Consent in children is an issue that causes great sensitivities. The reader is referred to the Department of Health guidelines (www.doh.gov.uk/consent) and trainee surgeons in particular are advised to seek the advice of senior colleagues in the event of any uncertainties.

KEY POINTS

- A clinic visit is a routine event for the doctor. It may be a major episode in the life of the parent and child.
- The organization of children's clinics require more space, more preparation and more attention to detail than is the case for adult clinics.
- Everyone can learn better consultation skills.
- Consent is a sensitive issue in children.
- Clinicians need to be familiar with the law in the jurisdiction in which they work and with best practice.

Best clinical practice

- ✓ Prepare for the consultation before the child comes into the examining room.
- ✓ Always introduce yourself to the parent and child.
- ✓ Explain the current knowledge base for every proposed intervention and listen to the views of the parent/child.
- ✓ A suitable range of flexible and rigid endoscopes, with facilities for safe storage and ideally a monitor and image capture system should be available, not just for specialized airway or voice clinics, but as a routine requirement for any paediatric consultation.
- ✓ It is important to know the procedures to be followed in the event of concerns about child protection, and the law on consent for the jurisdiction in which you work.

Deficiencies in current knowledge and areas for future research

- Parents are becoming more and more involved in decision making for their children in health care. The old patriarchal model of medical practice is fast disappearing. Doctors will need to discuss the natural history of diseases, treatment options and the uncertainties around evidence for existing practices in much greater detail than before.

SEARCH STRATEGY

The opinions in this chapter are supported by a Medline search using the key words cerebral palsy, mental retardation, handicap, special needs, Down syndrome, hearing loss, hearing aids, obstructive sleep apnoea/disorder, adenoidectomy/tonsillectomy, tracheostomy, drooling, sialorrhoea.

INTRODUCTION

Developments in neonatology and improved paediatric intensive care management are such that more infants with extreme prematurity or multiple organ pathologies now survive.¹ Similarly, modern treatments of many genetic and congenital diseases have improved outcomes. A proportion of such infants and children will have multiple medical conditions. These include neuromuscular dysfunction, sensory impairment including deafness, communication disorders and developmental delay. Epilepsy and learning disability are also more common in this group of children.¹

The prospect of managing a child with special needs may appear daunting, and is often associated with disappointing outcomes. However, in the appropriate clinical setting and with the intent of attaining maximal objective evidence to support a proposed intervention, the disappointment will be minimized. Down syndrome (trisomy 21) raises many of the issues common to managing ENT problems in children with special needs (Figure 64.1 and Table 64.1).

Terminology

The Oxford English dictionary defines a 'handicap' as a condition that markedly restricts a person's ability to function physically, mentally or socially. A 'disability' is a physical or mental condition that limits a person's movements, senses or activities. Some parents and children in the UK in particular dislike the terms handicap and disability as they feel these emphasize negative aspects of the child's needs and potential. The term 'special needs' is now more commonly accepted but much of the literature still relates to children with disabilities or multiple handicaps and these terms are widely accepted internationally.

CLINICAL ENVIRONMENT

An increasing proportion of clinical time is spent by the paediatric otolaryngologist-head and neck surgeon as part of a multidisciplinary team in the provision of

treatment to children with special needs, usually in a tertiary setting.

It is neither possible nor desirable to adequately assess a child with multiple pathologies in a general paediatric ENT clinic. These children often have clinical records that extend to several volumes, which require time for meaningful review. It is, therefore, desirable to set aside a specific clinic for evaluating children with special needs. Needless to say this clinic should be conducted by the consultant or senior attending physician. Even with the best clinic administration, some children will ‘slip through the net’ into a general clinic. It is the author’s

practice to explain such an error to the parents/carer and, if appropriate, reschedule the planned consultation. It goes without saying that wheelchair access, facilities for oxygen delivery, and seats for parents/carers and siblings are mandatory.

Clinical examination may be especially challenging; a skilled paediatric nurse is invaluable.

COMMUNICATION AND RAPPORT

The parents/carers of these children are often highly discerning and probe carefully the merits and risks of any proposed medical or surgical intervention. On occasion, more time is required to explain why an accepted surgical intervention may not be appropriate for a child than would be spent obtaining informed consent for that same procedure. The carers and children have multiple interactions with health care staff and will often develop a warm rapport with clinicians. Many will be familiar with the details and expectations of often-rare syndromes and will be affiliated with parent/carer groups that provide information and enable parents to discuss issues common to particular conditions with each other. In Britain, a joint project between parents and carers and the Royal College of Paediatrics and Child Health – ‘Contact a Family’ – maintains a website (www.cafamily.org.uk) which provides information and support for families of children with a variety of specific conditions.

Planned surgery

It should be remembered that the child with multiple pathologies will usually represent a greater anaesthetic and surgical risk with increased postoperative morbidity. They require the skills of a paediatric anaesthesiologist and may be unsuitable for same-day hospital care – overnight stay or even longer may be required predominantly due to delay in re-establishment of adequate oral intake and increased respiratory complications of

Figure 64.1 Child with Down syndrome.

Table 64.1 ENT problems in Down syndrome.

General	The airway	Ear disorders
Frequent upper respiratory tract infections (URTI)	Airway obstruction	Deafness
Thyroid disease	Narrow subglottis and trachea – may need smaller endotracheal tube during anaesthesia	Frequent acute otitis media and otitis media with effusion
Sialorrhoea	Midfacial hypoplasia – increased incidence of obstructive sleep apnoea syndrome (OSAS)	Small pinna and external meatus
Atlantoaxial instability (manipulate the head with extreme care under anaesthesia)	Hypotonic pharyngeal airway	Premature ossification of the cochlea
	Macroglossia	Facial nerve dehiscence common
		Ossicular fixation
		Mondini malformation more common

anaesthesia.² Some will need paediatric intensive care facilities postoperatively and this will need to be planned in advance. Often they require multiple surgical input, e.g. dental treatment, ear surgery and attention to a gastrostomy, and it may be appropriate to coordinate any planned ENT intervention with other treatments/disciplines.

What are routine investigations in the otherwise healthy child may require general anaesthesia in the child with multiple pathologies.

GENERAL CONSIDERATIONS

Common childhood ENT disorders may significantly interfere with the normal development of any child and their impact may be significant. In the child with special needs these common conditions may have a disproportionate impact on development and family life. Conversely, apparently minor clinical gains may have dramatic impacts for the child and their parents/carers, e.g. reduced nocturnal seizures following treatment of obstructive sleep disorder or improved hearing following grommet insertion.

In the child with special needs the maxim remains: maximize input in order to facilitate development to maximum potential. [**/*]

Ethical issues

It is necessary to address some difficult ethical issues when treating children with special needs. These children will naturally make greater demands on the health-care system, irrespective of the quality of care. 'There is no point in treating children like this.' 'The resources spent treating children like this would be better spent elsewhere.' These are common comments that are often heard in relation to the management of such children. It goes without saying that such opinion must never be communicated in any way to the patient or the parent/carer.

A full discussion of the ethical and health economic issues is beyond the scope of this chapter; nevertheless, some practical guidelines are required.

It is probably better if health-care professionals who hold negative opinions regarding intervention, irrespective of their role, excuse themselves from the management of these children; to do otherwise is inviting problems.

Prognosis

The available evidence related to the care of these children is predominantly in the form of retrospective case series. [**/*] Other than for some specific conditions, prognosis

is often uncertain. There are some crude indicators: the necessity for nasogastric tube feeding is a significant adverse prognostic indicator, interestingly unaffected by conversion to gastrostomy feeding. Paradoxically, the addition of a tracheostomy (despite its inherent mortality and morbidity) in the presence of nasogastric/gastrostomy feeding improves outcome, presumably due to improved access for bronchial toilet.³ These indicators obviously only relate to the most severe end of the spectrum; however, such information may facilitate difficult decisions for parents/carers. Otherwise there is little evidence base to support interventions, other than that available for such interventions in otherwise healthy children.

The prognosis of many childhood medical conditions, for example cystic fibrosis, metabolic diseases, renal failure and congenital cardiac lesions, has been greatly improved by active intervention and the involvement of multidisciplinary teams.¹ [****/*]

It has been demonstrated in other areas that timely intervention may in the long-term reduce expenditure (cf. Chapter 70, Paediatric cochlear implantation). Whilst outcome measures are difficult to assess, there is now evidence that multidisciplinary intervention in children with Down syndrome improves intermediate/long-term hearing outcomes.⁴ [**/*]

THE EAR AND HEARING

Assessment

Evaluation of the auditory pathway in the child with multiple pathologies may prove challenging, but is essential in overall management. Many referrals of these children will be from developmental paediatricians who wish to exclude significant hearing loss from a child's spectrum of disability (and also as part of a screening protocol for 'at risk' infants). Where access for audiological assessment is provided without direct assessment by a paediatric otolaryngologist-head and neck surgeon, systems must be in place to initiate appropriate clinical assessment and habilitation/rehabilitation of an identified hearing loss. Conventional age-appropriate audiological evaluation is performed with the understanding that results may not be accurate and that general anaesthesia with objective audiological evaluation is more likely to be required. Under general anaesthesia, any external or middle ear component of the problem should be minimized simultaneously to provide maximal accuracy of obtained thresholds (e.g. ear toilet, myringotomy plus/minus grommet insertion). Little controversy exists when it comes to obtaining accurate hearing thresholds, and apportioning conductive/sensorineural components to hearing loss. The same is not true when it comes to management.

Management

Concern has been raised with respect to the use of ventilation tubes in children with special needs, in particular Down syndrome. Some reports have documented a higher rate of morbidity following ventilation tubes in these children, notably otorrhoea and residual perforation.⁵ Overall, however, the majority of children in these reports still benefit from intervention. [**]

The narrow external meatus and the often difficult anatomy of the ear canal associated with Down syndrome make any transcanal middle ear surgery technically difficult (if not impossible); the narrow, and often hairy, meatus also contributes to failure of clearance of skin debris and wax. The proposed alternative is to use amplification for the management of hearing loss; this may prove to be a very acceptable alternative for some children. Often children with Down syndrome develop sensorineural loss in the teenage years and if amplification is anticipated this may be an argument for considering it earlier.

Amplification is not trouble-free. The presence of a hearing aid mould in a congenitally narrow and hairy external meatus may predispose to wax impaction and recurrent otitis externa – ear toilet will often require general anaesthesia in such children. Amplification may not, therefore, have the desired effect of avoiding otorrhoea and/or intervention under general anaesthesia. A rarely mentioned issue with respect to amplification is the small, but potentially disastrous, risk of ingestion of hearing aid batteries by the wearer or a sibling; this should be communicated to parents/carers.⁶ The judgement is individual to each child and will involve full discussion of the advantages and disadvantages with the parent/carer and child if he/she is old enough to participate in the decision. [*]

If amplification is the chosen modality for treatment, then regular observation is required for the early detection of the development of retraction changes/atelectasis, which should prompt reconsideration of surgical intervention.⁵

Cholesteatoma

Childhood cholesteatoma is a miserable condition for the patient, the parent/carer and all but the most enthusiastic otologist; this is even worse in the child with special needs. Not least of the expected problems encountered when cholesteatoma occurs is the unusual temporal bone anatomy associated with some syndromes, for example Down syndrome.⁷ Computed tomography (CT) scanning is essential to anticipate anatomical anomalies and facilitate planning surgical management – a conventional post-aural approach is ill-advised if there is a sclerotic mastoid, with middle fossa dura at the level of the second genu of the facial nerve. Peroperative facial nerve monitoring is especially valuable in this group. [*] In

view of the difficulties associated with cholesteatoma, it is the author's practice to treat retraction pockets/atelectasis aggressively in an incremental manner: from ventilation tubes and management of nasal conditions, to excision and reinforcement grafting. [*]

Otalgia

Recurrent otalgia, particularly at night, is a common feature of otitis media. This symptom may result in sleep deprivation for the child and family. It may also cause daytime behaviour problems, e.g. head-banging. Prolonged conservative management will not alleviate this situation which will often have been present for some time before otherwise asymptomatic middle ear disease is identified. Surgical intervention in the form of tympanostomy tube insertion may have dramatic benefit in such a circumstance. [**/*]

THE UPPER AERODIGESTIVE TRACT

Issues relating to feeding problems, drooling, stridor, nocturnal airway obstruction, dysphonia, aspiration and long-term airway access, may all present either as a single entity or in any combination.

Feeding problems

Most tertiary paediatric institutions have 'feeding teams'. These teams comprise paediatric gastroenterologists, paediatric neurologists, speech and swallowing therapists, dieticians and psychologists. They will manage issues related to feeding from the time of discharge from the neonatal unit through to adolescence. The paediatric otolaryngologist-head and neck surgeon will therefore usually only become involved with purely feeding issues when a surgical problem has already been identified or when feeding problems are associated with aspiration requiring tracheostomy for bronchial toilet. Great care must be taken when explaining to a parent/carer the postoperative management required when tracheostomy is performed for this reason: continued aspiration of oropharyngeal secretions is likely to occur and increase demands for tracheostomy care. Some parents/carers may, on reflection, decline the option of tracheostomy. In this instance, an upper endoscopy should be recommended in order to exclude any other structural or functional abnormality (other than neuromuscular incoordination) contributing to aspiration. If not already performed, a thorough upper endoscopy is mandatory prior to tracheostomy for the same reasons; particular care must be given to the exclusion of an occult laryngeal cleft by the use of an appropriate laryngeal probe for palpation of the posterior glottis and cricoid cartilage (**Figure 64.2**).

© Hodder Arnold / Scott-Brown 7E

Figure 64.2 Blunt laryngeal probe and measuring device (Lowinger laryngeal probe; Xomed-Medtronic) – useful in older infants and children; not readily manipulated in smaller laryngoscopes where a fine blunt suction probe will suffice.

Often by the time tracheostomy is performed, some degree of reduced respiratory reserve is present; however, once past the anaesthetic and perioperative period, there is often apparent improvement in respiratory function due to reduced dead space and reduced airway resistance. Whilst this apparent improvement remains it may provide considerable respite for the parent/carer.³

Laryngotracheal disease

Dysphonia and stridor will often be wrongly attributed to neuromuscular problems intrinsic to the child's overall condition. It is important that the paediatric otolaryngologist–head and neck surgeon should not perpetuate such assumptions; thorough upper endoscopy is required as would be the case for otherwise healthy children. It must be emphasized, however, that any concomitant neuromuscular incoordination will adversely impact upon therapeutic interventions – it is always difficult to be precise about the degree of this adverse impact, and not just because of the varying degree of neuromuscular incoordination. For example, correction of a subglottic stenosis may have a disappointing outcome due to arytenoid prolapse secondary to neuromuscular incoordination; changing the dynamics of the upper airway may have a very unpredictable outcome. Nowhere is this principle better illustrated than in the management of snoring and sleep-related airway obstruction.

Obstructive sleep apnoea

The simplistic notion that snoring equates to adenotonsillar hypertrophy and that each child may be safely treated with adenotonsillectomy will result in disappointment more commonly in the child with multiple pathologies than in the general paediatric population.⁸ Adenotonsillectomy alone fails to reduce the Respiratory Disturbance Index below 5 in approximately 15 percent of children undergoing surgery for a presumed obstructive sleep disorder;⁹ and it is into this group that the child with multiple pathologies is more likely to fall.⁸ Airway noise is

common in these children and is often a respiratory monitor for parents/carers! It is always worth directly enquiring about features of nocturnal airway obstruction, but the usual clinical features (which are notoriously unreliable in the healthy child⁹) may be even more difficult to interpret in the child with a complex medical history. Initial examination should include consideration of dysmorphic features and neuromuscular coordination in addition to the more usual clinical examination. Simple measures to eradicate any bacterial rhinitis or to institute treatment for atopy should be used as appropriate. The myriad of potential causes of sleep disruption, some of which may coexist with an element of an obstructive sleep disorder, makes clinical judgement suspect. Formal polysomnography may prove extremely helpful in the selection of children who are likely to benefit from intervention; it may also identify other causes for sleep disruption.¹⁰ It is common practice for a parent/carer to board with their child for this investigation; the validity of the investigation may be assessed by asking the parent/carer if the night of the sleep study was a typical night for their child. If polysomnography demonstrates significant obstruction, then the next step is to determine the level of that obstruction. Once again it is important to emphasize that whilst adenotonsillar hypertrophy may be significant, and indeed adenotonsillectomy is likely to be the intervention of first choice, other causes of airway obstruction are more likely to coexist.¹¹ Sleep endoscopy has been suggested to facilitate localization of the level of obstruction, which is more likely to be multiple in this type of patient. This procedure requires experience to be of value, but may demonstrate unexpected levels of airway compromise; and may be of particular importance following failed earlier intervention.¹² Syndromic children are more likely to require tracheostomy in the management of an obstructive sleep disorder, for example, Crouzon syndrome (**Figures 64.3** and **64.4**). However, it may be possible to avoid tracheostomy by management of other levels of obstruction. Modified conservative uvulopalatopharyngoplasty (UPPP),^{8, 13} tongue base reduction, hyoid suspension¹⁰ and laser aryepiglottoplasty¹⁴ may have a role depending on the findings at sleep endoscopy. [**/*] Using a stepwise incremental targeted procedure has been reported to avoid tracheostomy in up to 80 percent of children with cerebral palsy.¹⁰ Great caution must be taken with any procedure that has the potential to impact upon velopharyngeal function; there is a much higher risk of postoperative velopharyngeal insufficiency in this group of children.¹⁵ Partial (or superior) adenoidectomy using an endoscopic-powered debriider may minimize this risk.^{16, 17} [**/*]

The multidisciplinary sleep clinic

It is the author's practice to coordinate each stepped intervention with the paediatric sleep physician; partial

© Hodder Arnold / Scott-Brown, 7E

Figure 64.4 Successful decannulation of child in Figure 64.3 following midfacial advancement.

surgical successes may permit the use of positive airway support devices that had previously been unsuccessful. It is the author's experience that an increasing number of such children require multimodality therapy to adequately control nocturnal airway obstruction without tracheostomy.

Many special needs children have sleep disorders not due to airway obstruction. These may have a profound impact on quality of life for families. Optimum treatment of these disorders involves an interested paediatrician and a multidisciplinary team.¹⁰

DROOLING

Drooling, or sialorrhoea, is physiological in the early part of life. It will occur in relation to teething, oropharyngeal ulceration and upper respiratory tract infections/upper aerodigestive tract infections. Physiological drooling usually settles around the age of two years when the primary dentition has erupted; however, it may persist on a minor basis in some children up to the age of four. This physiological occurrence is minor by comparison to the sialorrhoea that may occur with cerebral palsy and other forms of severe neurological impairment. Approximately 10 percent of children with cerebral palsy will have problematic drooling.¹⁸ In order to determine this it is necessary to question the parent/carer regarding their management of the drooling – how many times are changes of clothes required per day; are 'quilted' bibs required for management? Some carers will complain that the school-going child soils books and papers and in older children there is the added difficulty of peer acceptance. If the condition has little impact on clothing management, then the drooling is minimal and simple reassurance will usually suffice. The resourcefulness, and tolerance, of parents/carers in dealing with this problem never ceases to amaze the author! Excessive drooling will macerate skin and therefore give rise to dermatological problems around the mouth and along the line that gravity carries it on an individual child. It can be a miserable problem for both parents and the child. General examination should include consideration of posture as well as a full otolaryngology evaluation. Particular consideration should be given to evaluation of nasal obstruction, and the presence of oropharyngeal ulceration (including gingivitis), which may be overlooked or considered noncontributory in the presence of severe neurological impairment.

Treatment

Nonsurgical treatments are often disappointing, and have usually failed by the time a child arrives at the paediatric otolaryngologist-head and neck surgeon. Anticholinergic agents to reduce salivary flow are often poorly tolerated

due to nausea, and ocular side effects. Speech and swallowing therapy should also have been tried for a period of six months; occasionally simple posture changes (sometimes using appliances) will improve oral continence.¹⁹

Surgical treatments utilize the concepts of: the division of parasympathetic neurological supply to major salivary glands; mechanical obstruction of the salivary ducts; and redirection of salivary flow.

Neurectomy

Division of the anterior branches of the tympanic plexus on the promontory via a relatively simple tympanotomy will reduce, but not eliminate, secretions from the parotid gland. It should be remembered that these branches (usually two) may be covered by a thin layer of bone (more commonly the anterior branch). This necessitates formal identification and division of two nerves in the mucosa overlying the promontory; failing this, a micro-drill is used to find the branch(es) which are always superficial in the bone.²⁰ It is also possible to reduce the parasympathetic drive to the submandibular salivary gland with simultaneous division of the chorda tympani nerve; however, this necessitates removal of taste from the anterior two-thirds of the tongue. In a child who already has severe limitation of sensory input, it may be difficult to justify the deliberate removal of one route of input. It can be difficult to obtain informed consent, particularly given the usually disappointing results produced by this intervention.²¹ In its favour, this technique can be performed bilaterally, with little in the way of post-operative morbidity. The author no longer recommends or performs denervation procedures unless it is the preferred option of the parent/carer. [**/*]

Botulinum toxin

Botox has been used by some authors. Direct injection into the parotid and submandibular glands may reduce salivary flow.²² Evidence is currently sparse and controlled trials are needed before this can be recommended for routine clinical use.

Mechanical diversion or obstruction of salivary flow

Overall, mechanical diversion or obstruction of salivary flow from the major glands is reported to produce the best outcomes.

Ligation of the submandibular and parotid ducts is reported to be an effective treatment, with surprisingly few sequelae. The procedure is performed intraorally, with postoperative antibiotic prophylaxis. The glands

initially swell and subsequently undergo atrophy.²³ It is interesting to note that a radionuclide study of submandibular gland function following duct transposition reported 50 percent of the glands are atrophied and nonfunctioning following surgery.²⁴

In the past 20 years or so, transposition of the submandibular ducts to the tonsillar fossae has become the most popular and reported procedure for drooling. From its initial description, the procedure has been refined to include intraoral excision of the sublingual salivary glands. The sublingual glands drain via the distal portion of the submandibular salivary duct; therefore leaving the sublingual glands *in situ* may predispose to postoperative ranula formation. Tonsillectomy (if not already performed) is carried out as part of the procedure to facilitate duct transposition. There is often significant postoperative swelling and significant postoperative morbidity may occur. Parental satisfaction is very high with this procedure.¹⁹ Long-term follow-up suggests that improvement in drooling is maintained.²⁵ There are reports of increased dental caries following submandibular duct transposition; this is presumed to be due to loss of the salivary 'puddle'.^{26,27} It should be mentioned to parents/carers that there will be the need for diligent dental hygiene and increased risk of dental caries following transposition of the submandibular ducts. [**/*]

KEY POINTS

- Children with special needs require extra time for clinical evaluation.
- The maxim remains: maximize sensory input in order to maximize achievement of potential.
- Apparent small clinical gains may have dramatic benefits for the child and family.
- Where possible, maximal information should be obtained to support planned intervention.
- Conventional intervention is less likely to produce the anticipated outcome in a child with special needs.

Best clinical practice

- ✓ Rehabilitation of hearing presents special challenges in this group of children and management must be tailored for a particular child.
- ✓ Airway obstruction is more likely to be complex and multilevel in syndromic children.

- ✓ Submandibular duct transposition with excision of the sublingual glands is the current procedure of choice for excessive drooling.
- ✓ Children with Down syndrome present challenges to otolaryngologists and anaesthesiologists and special care is needed when considering surgery in this group.

Deficiencies in current knowledge and areas for future research

- There is an increasing trend to centralize the care of special needs children around a tertiary centre where support services including paediatric anaesthesia are available.
- Developmental paediatrics is a growing specialty; better classification of developmental disorders and attendant improvements in predicting outcome are already underway.
- Multidisciplinary involvement – essential to the optimum management of these children – will improve outcome and hopefully the evidence base for treatment.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words head, skull, ear, nose, palate, tongue, tooth, salivary gland, neck, thyroid, pharynx, oesophagus and larynx and focussing on level 1 evidence on embryology, growth and development. Morphological details are described and their relation to embryological stages, size and age are summarized in **Table 65.1**. References to the underlying genetic and molecular mechanisms governing embryological development are cited.

GENERAL EMBRYOLOGY

Development begins with fertilization when the sperm and oocyte, each haploid with 23 chromosomes, unite to form the diploid zygote containing 46 chromosomes. Chromosomal abnormalities and gene mutations cause major craniofacial defects. Three, rather than two, copies of chromosomes cause trisomy syndromes – trisomy 13, 18 and 21 (Down syndrome). Partial chromosome deletions result in cri-du-chat syndrome (chromosome 5), Angelman syndrome (chromosome 15), Miller–Dieker syndrome (chromosome 17) and Shprintzen syndrome (chromosome 22). Breakage of chromosomes (fragile X syndrome) and gene mutations (MSX2) also cause craniofacial abnormalities.²

The zygote divides, producing a morula which cavitates to form a blastocyst that implants in the endometrium during the second week. The inner cell mass of the blastocyst gives rise to the embryo. Initially the inner cell mass forms a bilaminar germ disc which then, by gastrulation, leads to a trilaminar disc comprised of ecto-, meso- and endoderm layers in week 3 (**Figure 65.1**). Weeks 3–8 comprise the embryonic period during which the main organ systems are established and are vulnerable to teratogens such as drugs (thalidomide, alcohol), infectious agents (rubella, HIV) and physical agents (x-rays) which can cause major birth defects.

Ectoderm gives rise to tissues and organs which maintain contact with the outside world – the nervous system, skin, the sensory epithelium of the ear, nose and

Table 65.1 Carnegie embryonic stages in the development of the human head and neck, based on ultrasonic studies.¹

Stage	Age (days)	Size (mm)	Major features
1	1	0.1–0.15	Fertilization
5	7	0.1–0.2	Implantation
8b	23	1.01–1.5	Neural folds and groove appear

eye, and tooth enamel. Neurulation is the process by which ectoderm forms a neural plate that folds to form the neural tube, giving rise to the brain and spinal cord, and the neural crest (**Figure 65.2**). Neural crest changes into mesenchyme and contributes to the connective tissue and bones of the face and skull.

Lateral to the neural tube, paraxial mesoderm forms pairs of somites each of which give rise to its own sclerotome (bone and cartilage), myotome (muscle) and dermatome (dermis) component. The occipital bone and cervical vertebrae are derived from sclerotomes, and the related myo- and dermatomes are segmentally innervated. Endoderm provides the epithelial lining of the gastrointestinal and respiratory tracts, including the tympanic

Figure 65.1 Highly diagrammatic representation of a longitudinal section of the developing embryonic disc. The structure never looks like this at any one time since development is progressing at different rates. Nevertheless, mesoderm lies between ectoderm and endoderm, except at the buccopharyngeal and cloacal membranes where the two layers are in contact. The notochord, a derivative of the ectodermal layer, lies within the mass of mesoderm. A connecting stalk attaches the developing disc with its amniotic cavity and yolk sac to the uterine wall, and these structures lie within the extra-embryonic coelom at this stage of development.

Figure 65.2 Transverse section of the developing embryonic disc at various stages of development. In the early presomite stage (a) a midline neural groove is present above the notochordal plate, which is fused with the endodermal layer. The neural groove deepens (b) and specialized neural crest cells develop on the lips of the groove. The notochord separates from the endodermal layer. By the somite stage (c) the neural tube has formed and the neural crest cells are about to migrate to form cell clusters which, at the head end of the embryo, become the cranial sensory nerve ganglia. Cells from the neural crest also form the posterior root ganglion of the spinal cord and the cells of the sympathetic ganglia.

cavity and auditory tube, and the parenchyma of the thyroid and parathyroid glands.

The foetal period runs from the ninth week of gestation until birth at 38 weeks of gestation or 40 weeks after the onset of the last menstruation and is characterized by growth and maturation of tissues and organs. Abnormalities may result from disruption of blood supply or mechanical deformation. Major congenital malformations, due to genetic, environmental or, most commonly, unknown causes, occur in approximately 4 percent of live births, but minor abnormalities are found in a further 15 percent.³ A *syndrome* is a group of anomalies occurring together with a specific common cause, while in an *association* this cause has yet to be determined. Due to the common germ layer origin of a variety of organs, or the contemporaneous development of different systems, the presence of minor abnormalities may indicate more serious underlying defects. This is particularly true of external ear abnormalities which feature in most common chromosomal syndromes.²

SKULL

Skull development is influenced by both genetic factors and the mechanical forces generated by brain growth, development of the pharynx and muscle activity. The skull is divided into the neurocranium, which protects the brain, and the viscerocranium, derived from pharyngeal arches, which forms the face and jaws. Both neurocranium and viscerocranium ossify partly by intramembranous and partly by endochondral ossification.¹ In intramembranous ossification, mesenchyme differentiates directly into bone. This mesenchyme is derived from neural crest cells in the roof and sides of the skull and from paraxial mesoderm in the occiput and posterior otic capsule. Primary ossification centres appear as spicules in the centre of these flat bones and radiate to the periphery. At birth, membranous sutures separate these bony plates, enabling moulding to occur during birth. Osteoblasts lay down new bone on outer surfaces and osteoclasts resorb bone from inner surfaces to permit the vault to grow and accommodate the expanding brain. Where sutures meet at the angles of the parietal bone are six membranous intersections, termed *fontanelles*. The largest is the anterior fontanelle at bregma, between the parietal and frontal bones, which is a useful indicator of raised intracranial pressure or dehydration and provides access to the underlying superior sagittal venous sinus. It is obliterated by two years, while the posterior fontanelle at lambda, between the parietal and occipital bones, closes at about six months after birth.⁴

Premature closure of sutures results in craniosynostosis.⁵ Early closure of the coronal suture causes acrocephaly, or tower skull; early closure of the sagittal suture causes a long narrow skull, scaphocephaly (**Figure 65.3**) and unilateral premature closure of the coronal and

(a)

(b)

Figure 65.3 Scaphocephaly. In this child the sagittal suture is completely fused, while the remaining sutures of the cranial vault are normal.

lambdoid sutures results in asymmetry – plagiocephaly (see Chapter 78, Craniofacial anomalies: genetics and management).

In endochondral ossification, mesenchyme forms a cartilaginous model which is then replaced by bone. Anterior to the pituitary gland in the midline, neural crest cells give rise to the ethmoid, inferior nasal concha and body of the sphenoid. Posterior to the pituitary, paraxial mesoderm forms the clivus and base of the occipital bone.

Laterally, the ala orbitalis and ala temporalis form the lesser and greater wings of the sphenoid, while the otic capsule develops around the membranous labyrinth and gives rise to the petrous and mastoid parts of the temporal bone.² The sphenoccipital junction remains cartilaginous until puberty, while the cartilage of the foramen lacerum does not undergo ossification. Incomplete ossification may lead to herniation of the meninges, or meningocele, but larger defects can include neural tissue (meningoencephalocele) (see Chapter 78, Craniofacial anomalies: genetics and management) or even brain and part of a ventricle (meningohydroencephalocele).²

The viscerocranium, forming the face and jaws, is derived from the first two pharyngeal arches.

PHARYNGEAL ARCHES

Arches of mesenchyme derived from paraxial and lateral plate mesoderm and neural crest cells appear in the fourth and fifth weeks of development. They are covered externally by ectoderm, which forms clefts between successive arches, and internally by endoderm which forms pouches between arches. Morphologically, they resemble gills in fish, but as true gills (branchia) are never formed, the term pharyngeal arches is used in humans. Pharyngeal arches play a role in the formation of the face, ear and neck (**Figure 65.4**) and their derivatives are summarized in **Table 65.2**.⁵

Modified from Ref. 2, with permission.

First pharyngeal arch

The first arch has a dorsal maxillary process and a ventral mandibular process. The maxillary process gives rise to the premaxilla, maxilla, zygomatic bone, the zygomatic process and squamous part of the temporal bone by intramembranous ossification. The mandibular process contains Meckel's cartilage which persists as the malleus, anterior ligament of malleus, incus and sphenomandibular ligament. The majority of the mandible is formed by membranous ossification of mesenchyme around Meckel's cartilage. This entraps the inferior alveolar branch of the mandibular nerve which enters the bone through the mandibular foramen. Its terminal branch, the mental nerve, exits via the mental foramen. The right and left mandibular processes meet in the midline at the symphysis menti which achieves bony union six months after birth.⁴

The trigeminal (V) nerve supplies sensation to the first arch connective tissues via its ophthalmic, maxillary and mandibular branches. Only the mandibular division has a motor root and supplies eight first arch muscles: four muscles of mastication (temporalis, masseter, medial and lateral pterygoid), two tensors (tympani and palati), mylohyoid and the anterior belly of digastric.

Second pharyngeal arch

The second arch gives rise to the stapes, styloid process of the temporal bone, stylohyoid ligament, lesser cornu and upper body of the hyoid bone. The facial (VII) nerve supplies sensation to second arch connective tissue in the external auditory canal, but is mainly motor supplying: stapedius, stylohyoid, posterior belly of digastric, occipitofrontalis and the muscles of facial expression.

Third pharyngeal arch

The third arch gives rise to the greater cornu and lower body of the hyoid bone. The glossopharyngeal (IX) nerve supplies sensation to third arch connective tissues in the posterior third of the tongue and is motor to glossopharyngeus.

Fourth and sixth pharyngeal arches

The cartilaginous components of the fourth and sixth arches fuse to form the laryngeal cartilages: thyroid, cricoid, arytenoid, corniculate and cuneiform. The superior laryngeal branch of the vagus (X) supplies sensation to fourth arch connective tissue from the valleculae and epiglottis to the true vocal cords and is motor to levator palati, pharyngeal constrictors (partially) and

Table 65.2 Derivatives of the pharyngeal arches and pouches.^{1, 2, 5}

Arch	Skeleton	Nerve	Muscles	Artery	Pouch
First	Maxilla, Meckel's cartilage, malleus, anterior ligament of malleus, incus, sphenomandibular ligament, portion of mandible	V. Trigeminal mandibular division	Mastication (temporalis, masseter; medial and lateral pterygoids); mylohyoid; anterior belly of digastric, tensor palati, tensor tympani	Maxillary	Eustacian tube; middle ear cavity; Tubotympanic recess (first cleft forms external auditory meatus)
Second	Staples; styloid process; stylohyoid ligament; lesser horn and upper portion of body of hyoid bone	VII. Facial	Facial expression (buccinator; auricularis; frontalis; platysma; orbicularis oris; orbicularis oculi); posterior belly of digastric; stylohyoid; stapedius	External carotid	Bed of palatine tonsil
Third	Greater horn and lower portion of body of hyoid bone	IX. Glossopharyngeal	Stylopharyngeus	Common carotid and first part of internal carotid	Thymus; inferior parathyroid
Fourth–sixth	Laryngeal cartilages (thyroid, cricoid, arytenoid, corniculate, cuneiform)	V. Vagus. Superior laryngeal branch (nerve to fourth arch)	Cricothyroid; levator palati; constrictors of pharynx (fourth)	Aortic arch (fourth left)	Superior parathyroid (fourth)
		Recurrent laryngeal branch (nerve to sixth arch)	Intrinsic muscles of larynx (sixth)	First part subclavian (fourth right) Ductus arteriosus (sixth left) Proximal right pulmonary (sixth right)	Ultimobranchial body (fifth)

cricothyroid. The recurrent laryngeal branch of the vagus supplies sensation to sixth arch derivatives, notably the infraglottic larynx, and is motor to the other muscles of the larynx.

PHARYNGEAL POUCHES

On each side, between the six arches, lie five pharyngeal pouches lined by endoderm (**Figure 65.5**). Their derivatives are summarized in **Table 65.2**.

The first pouch extends laterally to form the Eustachian tube, the middle ear cavity and the tubotympanic recess, which extends as far as the tympanic membrane.

The second pouch forms the bed of the palatine tonsil.

The third pouch forms ventral and dorsal wings. The epithelium of the ventral wing differentiates into

the thymus, while that of the dorsal wing forms the inferior parathyroid gland. The thymus separates from the pharyngeal wall and descends inferomedially to unite with contralateral thymic tissue behind the sternum. The inferior parathyroid descends to lie posterior to the inferior pole of the ipsilateral thyroid lobe. Thymic tissue may be found embedded in the thyroid, while the inferior parathyroids may lie at sites from the bifurcation of the common carotid artery to the anterior mediastinum behind the sternum.

The dorsal wing of the fourth pouch differentiates into parathyroid tissue which descends to lie posterior to the superior pole of the ipsilateral thyroid lobe.

The fifth pouch (or ventral wing of the fourth) forms the ultimobranchial body, which is incorporated into the thyroid gland and gives rise to parafollicular calcitonin-secreting cells.

Figure 65.5 A diagram to show the development and derivatives of the pharyngeal pouches and clefts. Note the way in which the second, third and fourth clefts are buried and, if not obliterated, form the cervical sinus. 1A, first cleft; 1B, first arch; 1C, first pouch; 2A, second cleft; 2B, second arch; 2C, second pouch; 3A, third cleft; 3B, third arch; 3C, third pouch; 4A, fourth cleft; 4B, fourth arch; 4C, fourth pouch; 5C, fifth pouch; 6, maxillary process; 7, mandibular process; 8, epicardial ridge; 9, external auditory meatus; 10, cervical sinus; 11, pharyngotympanic tube; 12, palatine tonsil; 13, inferior parathyroid gland; 14, thymus; 15, superior parathyroid gland; 16, ultimobranchial body. Modified from Ref. 2, with permission.

Pharyngeal diverticulum

The structural weakness between thyropharyngeus and cricopharyngeus, Killian's dehiscence, may be the site of an acquired pulsion diverticulum which may be described erroneously as a 'pharyngeal pouch'.⁶

As neural crest cells contribute to both pharyngeal and heart formation, craniofacial and cardiac abnormalities are common to a number of syndromes (see Chapter 78, Craniofacial anomalies: genetics and management). First arch structures are affected in Treacher Collins and Goldenhar syndromes (see Chapter 80, Facial paralysis in childhood), and the Pierre Robin sequence. The DiGeorge sequence affects the third and fourth pouches, as well as the first arch and external ears.^{1, 2}

PHARYNGEAL CLEFTS

On each side, between the first five arches, lie four pharyngeal clefts lined by ectoderm. Normally, only the first cleft persists and its dorsal end gives rise to the external auditory meatus, separated from the first pouch by the tympanic membrane. The ventral end is normally obliterated, but may persist as a sinus, cyst or fistula. Such a fistula extends from below the auricle, through the parotid gland and opens into the external auditory meatus. It has a variable relationship with the facial (VII) nerve.¹

The second arch overgrows the second, third and fourth clefts, forming the cervical sinus which then resorbs. However, if this sinus persists, it gives rise to cervical cysts along the anterior border of sternocleidomastoid (Figure 65.6).⁷ If the cysts communicate with the

skin, they form external branchial fistulae. The cervical sinus may also communicate with the second pouch in the bed of the palatine tonsil to form an internal branchial fistula. Such fistulae pass over the glossopharyngeal (IX) and hypoglossal (XII) nerves and run between the external and internal carotid arteries (Figure 65.7) (see Chapter 99, Branchial arch fistulae, thyroglossal duct anomalies and lymphangioma).^{1, 8}

The third cleft may give rise to a fistula extending from the anterior border of sternocleidomastoid, passing superficial to the hypoglossal (XII) nerve, deep to the carotid arteries and piercing the thyrohyoid membrane to open into the piriform fossa.⁸ Very rarely a fistula from the fourth cleft may extend from the anterior border of sternocleidomastoid, pass around the arch of the aorta on the left side, or right subclavian artery, ascend in the neck running superficial to the hypoglossal (XII) nerve, deep to the carotid arteries and open into the lower pharynx (see Chapter 99, Branchial arch fistulae, thyroglossal duct anomalies and lymphangioma).¹

FACE

The face develops from five growth centres or prominences – the frontonasal in the midline and the right and left maxillary and mandibular prominences. The frontonasal prominence forms the forehead and, inferiorly, lies above the primitive mouth or stomodeum with a nasal placode on either side. The nasal placodes invaginate to form nasal pits and their margins form lateral and medial nasal processes. The first arch gives rise to the maxillary prominences lateral to the stomodeum and the mandibular prominences inferiorly.⁹

Figure 65.6 A diagram to show a lateral cervical (branchial) cyst opening onto the surface as a fistula (a). (b) Location of cysts and fistulae anterior to the sternocleidomastoid muscle. (c) Internal opening of a fistula by the palatine tonsil. 1, external auditory meatus; 2, palatine tonsil; 3, lateral cervical (branchial) cyst; 4, external branchial fistula; 5, region of preauricular fistulae; 6, region of lateral cervical cysts and fistulae; 7, sternocleidomastoid muscle; 8, tubotympanic recess; 9, internal branchial fistula. Modified from Ref. 2, with permission.

The maxillary prominences grow medially, pushing the medial nasal processes towards the midline and fusing with them to form the upper lip (**Figure 65.8**). The philtrum is derived from the medial nasal process with the maxillary prominence providing the lateral lip and cheek. An alternative theory is that the maxillary prominences fuse in the midline superficial to the frontonasal prominence, thus accounting for the maxillary nerve supplying sensation to all of the upper lip, including the philtrum.¹ The nasolacrimal groove lies between the maxillary prominence and lateral nasal process. This groove separates, forming a duct, and allows the lateral nasal process and maxillary prominence to fuse.

The lower lip and jaw are formed by the fusion of the right and left mandibular prominences. The right and left halves meet anteriorly at the symphysis menti, but fusion, starting at the outer and inferior surfaces, is usually complete by six months after birth.⁴ The cheeks develop from the maxillary and mandibular processes which accounts for their sensory innervation. The musculature, however, is derived from mesenchyme of the second pharyngeal arch and so receives its motor supply from the facial (VII) nerve.

form the triangular primary palate which carries the upper medial and lateral incisors and extends posteriorly to the incisive foramen – the premaxilla of the adult. The secondary palate comprises the remainder of the adult hard and soft palates and is formed in three stages where the palatal shelves are, respectively, vertical, horizontal or fused.¹⁰ In stage I, vertical palatal shelves arise from the maxillary prominences and lie lateral to the tongue. The two shelves expand by cell division, hydration and electrostatic forces in the orofacial cavity which is growing in height but not in width.¹¹ Descent of the tongue as the first arch elongates, combined with shelf expansion, results in the elevation of the shelves to the horizontal position – stage II (**Figures 65.9**). This movement is rapid and occurs in a matter of minutes or hours.¹² In stage III, the palatal shelves fuse separating the nasal and oral cavities.¹² The epithelium on the superior, nasal surface is pseudostratified, ciliated columnar, while on the inferior, oral surface are stratified, squamous, nonkeratinizing cells.¹⁰ Bone that forms in the hard palate belongs to the maxillae and palatine bones. The soft palate and uvula probably develop by epithelial displacement due to mesenchymal activity, rather than by midline fusion.¹

PALATE

The palate separates the oral and nasal cavities and is formed in two phases, primary and secondary, under separate genetic and epigenetic controls (see Chapter 77, Cleft lip and palate).¹ The medial nasal processes fuse to

Facial clefts

Cleft palate may result from disturbances at any stage of palatal development.^{5,11} Failure of fusion of the maxillary prominence and medial nasal process gives rise to clefts anterior and posterior to the incisive foramen. Anterior clefts may involve the lip alone or include the palate, may

Figure 65.7 Operation for second branchial cleft fistula (a) showing two horizontal incisions, the lower one to include the fistulous opening; (b) the fistula is seen crossing the hypoglossal nerve to pass between the internal and external carotid arteries.

extend into the nose and may be bilateral.¹³ Posterior clefts lie in the midline and may involve the uvula alone, or separate both palatine shelves and extend into the nose. Anterior and posterior clefts may be combined. Cleft types are summarized in **Figure 65.10**.¹⁴ A variety of mechanisms have been implicated in clefting, with failure of shelf elevation occurring in the majority of cases.¹¹

Failure of fusion of the maxillary prominence and lateral nasal process exposes the nasolacrimal duct to form an oblique facial cleft. However, they may be due to irregular tearing accompanying rupture of the amnion.¹ Craniofacial clefts are summarized in **Figure 65.11**.¹⁵ Rarely, the medial nasal processes may fail to fuse causing a median cleft lip. The entrapment of epithelium along lines of fusion may result in nasolabial, globulomaxillary, median alveolar and median palatal cysts which usually do not present until adulthood (**Figure 65.12**).

Figure 65.8 The roof of the stomodeum of a 12 mm human embryo illustrating the development of the primitive palate and posterior nares by approximation of the maxillary processes to the lateral and medial nasal folds. The previous site of the attachment of the buccopharyngeal membrane is represented by a dotted line and part of the left maxillary process has been removed. After Hamilton WJ and Mossman HW (eds). *Human embryology*. Cambridge: Heffer, 1972.

MOUTH

The primitive mouth or stomodeum is bounded by the forebrain superiorly and the pericardial cavity inferiorly. The buccopharyngeal membrane separating it from the foregut breaks down and so connects the amniotic cavity and the primitive gut (**Figure 65.13**). The cranial part of the foregut, often termed the pharyngeal gut, thus extends from the buccopharyngeal membrane to the tracheo-bronchial diverticulum.² Laterally, pharyngeal mesenchyme segments to form the pharyngeal arches.

Salivary glands

Three pairs of salivary glands arise from the oropharyngeal epithelium and follow similar patterns of development to produce branching ducts and secretory acini.¹⁶ The submandibular gland originates as an epithelial cord in the groove between tongue and mandible which branches into the surrounding mesenchyme. Serous acini appear early, followed by mucous acini postnatally.^{1,17} The sublingual and parotid glands develop in a similar fashion, with the site of opening of the parotid duct dependent upon skeletal development. There is no evidence to suggest that the gland is composed of two lobes, rather the parotid ductules grow around the facial (VII) nerve, making it intimately entwined with the gland.¹⁸

Teeth

The epithelium of the oral cavity forms the dental lamina on the upper and lower jaws. On each jaw, ten diverticula

Figure 65.9 Section through the developing palate of (a) a 20-mm and (b) a 48-mm human foetus. Reprinted from Hamilton WJ and Mossman HW (eds). *Human embryology*. Cambridge: Heffer, 1972.

of the lamina push into the jaw mesenchyme giving rise to a permanent tooth bud and the dental bud from which a deciduous tooth develops in a complex interaction of genetic and epigenetic factors.¹⁹ The deep surface of each bud invaginates to form a dental cap lying on the dental papilla, a neural crest derivative. The cap comprises outer and inner epithelial layers separated by the stellate reticulum. The central part of the dental papilla forms the pulp of the tooth, while cells deep to the inner dental epithelium differentiate into odontoblasts which produce dentine and push themselves inwards into the papilla. The outer dental epithelial cells differentiate into ameloblasts which deposit enamel prisms over the dentine, beginning

at the apex and spreading towards the neck. As the enamel thickens, the ameloblasts are pushed outwards into the stellate reticulum (**Figure 65.14**).

The dental epithelial cells form a root sheath which expands into the jaw mesenchyme. Odontoblasts lay down dentine, continuous with that in the crown, which narrows the pulp chamber to a root canal. In the jaw mesenchyme, cells in contact with dentine differentiate into cementoblasts and secrete cementum. Outside the cementum, the periodontal ligament forms to connect the tooth to the jaw bone. None of the deciduous or primary teeth are impeded by covering bone and lengthening of the root causes the crowns to erupt in sequence from six

to 24 months after birth.²⁰ The permanent tooth buds remain dormant until the age of six years when they grow, pushing the deciduous teeth up and out.

Tongue

Two lateral lingual swellings from the first pharyngeal arch fuse with the midline tuberculum impar to form the anterior two-thirds of the tongue. In the posterior third, the third branchial arch overgrows the second. The V-shaped sulcus terminalis separates these regions with its apex at the foramen caecum from which the thyroid gland originates. General sensation to the anterior two-thirds of the tongue is from the lingual branch of the mandibular (V) nerve and taste from the chorda tympani branch of the facial (VII) nerve, while both taste and sensation to the posterior third are from the glossopharyngeal (IX) nerve. However, the glossopharyngeal nerve supplies taste and sensation to the vallate papillae anterior to the sulcus (Figure 65.15). Behind the posterior third lie the valliculae and epiglottis, fourth arch derivatives innervated by the superior laryngeal nerve from the vagus (X). The musculature is derived from four occipital somites innervated by the hypoglossal (XII) nerve.

Oropharynx and oesophagus

The formation of an oesophagotracheal septum divides the foregut into a respiratory diverticulum anteriorly and the oesophagus posteriorly (Figure 65.16). The oesophagus descends with the heart and septum transversum and so is lengthened. It is lined by endoderm which changes from stratified columnar in the embryo, to cuboidal and then to stratified squamous by birth, although ectopic gastric mucosa may also be present. The surrounding mesoderm gives rise to a muscular coat that is striated in its upper two thirds, innervated by the nucleus ambiguus of the vagus (X), and smooth in its lower two thirds and innervated by the dorsal nucleus of the vagus (X), via the oesophageal plexus.⁶ Peristalsis is immature at birth along the oesophagus and at the lower oesophageal sphincter, permitting regurgitation of food.

Deviation of the oesophagotracheal septum may give rise to oesophageal atresia and/or tracheoesophageal fistula. Atresia prevents passage of amniotic fluid into the gut resulting in hydrops, while five types of fistula may result.^{2, 21, 22} The most common comprises a blind upper oesophagus with the lower oesophagus joining the trachea near its bifurcation. In the second type, there is a

blind upper and lower oesophagus, with no connection (fistula) to the trachea. The third type consists of a proximal tracheoesophageal fistula with a blind lower oesophagus. In the H-type abnormality, there is a proximal and a distal tracheoesophageal fistula. In the fifth type, there is a tracheoesophageal fistula without oesophageal atresia (**Figure 65.17**). Vertebral, anal, tracheoesophageal and radial (VATER) abnormalities are frequently found in the same individual – a VATER association (see Chapter 101, Diseases of oesophagus, swallowing disorders and caustic ingestion).¹

NOSE AND PARANASAL SINUSES

The development of the medial and lateral nasal prominences causes the deepening of the nasal pits which open into the stomodeum between medial and lateral nasal processes (**Figure 65.8**). The nasal pits deepen to form nasal sacs which open at the anterior nares and will form the nasal cavities (see **Figure 104.1** in Chapter 104, *Anatomy of the nose and paranasal sinuses*). Posteriorly, the medial and lateral nasal processes fuse to form a nasal fin of epithelium which then regresses to leave the oronasal membrane caudally.²³ The development of the primary palate (premaxilla) and secondary palate, from the maxillary shelves, separates the oral and nasal cavities. Rupture of the oronasal membrane enables the nasal sac to communicate with the oropharyngeal cavity via the primary choanae. The definitive posterior choanae will lie further posteriorly due to palatal growth. Unilateral or bilateral choanal atresia may be due to persistence of the oronasal membrane or due to persistence of epithelial cells which normally plug the nasal cavity during the embryonic period (see **Chapter 82, Nasal obstruction in children**).^{23, 24}

A midline ridge develops from the posterior edge of the frontonasal prominence in the roof of the nasal cavity and extends posteriorly to the adenohypophyseal (Rathke's) pouch, which ascends from the roof of the oral cavity to form part of the pituitary gland (see **Figure 104.4** in Chapter 104 *Anatomy of the nose and paranasal sinuses*). Anteriorly, the septum is grooved forming the vomeronasal organ, which becomes a blind, tubular pouch 2–6 mm in length, involved in the sensation of pheromones.¹ The primitive septum is initially made

entirely of cartilage. The superior part ossifies to form the perpendicular plate of the ethmoid. Posteroinferiorly, the vomer ossifies from two centres on either side of the cartilage leaving two bony alae. The remaining septal cartilage is quadrilateral and lies anteroinferiorly, surmounted by the two nasal bones.

Conchal cushions appear on the lateral walls of the nasal cavity and fuse to form the conchae or turbinate bones. The superior and middle conchae originate with the ethmoid bone, while a supreme concha is present in up to one-third of cases. The inferior concha may be regarded as a separate bone, but functionally is a detached piece of the ethmoid.⁴ A depression or meatus develops beneath each concha and diverticula from these form the paranasal sinuses. The maxillary sinus arises from the middle meatus at the beginning of the foetal period, but most expansion develops after birth with development of the middle third of the face and eruption of the secondary dentition. A few ethmoid cells are present at birth and the frontal sinus, an enlarged anterior ethmoid air cell, invades the frontal bone after birth, while the sphenoid develops during childhood (**Figure 65.18**). The nasolacrimal duct appears along, but independently of, the border of the maxillary and frontonasal prominences to drain into the inferior meatus of the nose.

The frontal prominence gives rise to the bridge and septum of the nose, the fused medial nasal processes form the bridge and tip, while the alae are derived from the lateral nasal processes. Agenesis, clefting, duplication of the nose and supernumerary nostrils are anomalies of embryological development.²⁵

LARYNX

The respiratory system develops as a ventral outgrowth of the foregut and grows caudally, on a lengthening stalk.²⁶ The cephalic end of the stalk develops into the glottis and infraglottis, and the rest becomes the trachea. Above the respiratory diverticulum, pharyngeal mesoderm compresses the foregut lumen ventrodorsally as far cranially as the fourth pharyngeal pouches, forming an epithelial lamina with a narrow pharyngoglottic duct along its dorsal border. This mesoderm also raises an epiglottic and two arytenoid swellings in the pharyngeal floor at the level of the fourth pouches. The triangular laryngeal caecum is bounded by these swellings and grows caudally between the lamina and epiglottis. The epithelial lamina separates cephalocaudally, connecting the laryngeal caecum with the pharyngoglottic duct to form the laryngeal vestibule; when the separation is complete, the vestibule is continuous with the infraglottic cavity.²⁷ However, incomplete separation gives rise to congenital laryngeal webs (see **Chapter 88, Congenital disorders of the larynx, trachea and bronchi**).²⁸ Meanwhile, bilateral pouches arising from the caudal end of the caecum form the

ventricles, the lower lips of which become the vocal folds. The vestibule and ventricles receive sensory innervation from the internal branch of the superior laryngeal nerve of the fourth arch, while sensation to the infraglottic larynx is from the recurrent laryngeal nerve of the sixth arch. Motor supply is from the recurrent laryngeal nerve, with the exception of cricothyroid muscle which is

supplied by the external branch of the superior laryngeal nerve.

Pharyngeal mesoderm surrounding the laryngeal cavity gives rise to the laryngeal cartilages and intrinsic musculature. The laryngeal cartilages are derived from the fourth and sixth pharyngeal arches. The cricoid chondrifies bilaterally from a single centre in the ventral arch of a precartilaginous template which encircles the infraglottic cavity, and on meeting forms the dorsal lamina. Each arytenoid chondrifies from a single centre and each lamina of the thyroid cartilage chondrifies from two.^{27, 28} At birth, the epiglottis is close to the soft palate and apposition of the two structures can close off the oral cavity, so protecting the airway during suckling when breathing and drinking occur simultaneously.¹

THYROID GLAND

A diverticulum develops behind the tuberculum impar of the tongue and descends anterior to the pharynx and hyoid bone. It then ascends deep to the hyoid and descends again anterior to the thyroid and cricoid cartilages to the level of the upper tracheal rings and expands to form lateral lobes connected by a central isthmus. Epithelial cells develop into thyroid follicles, with hormone synthesis beginning early in the foetal period.¹ The ultimobranchial body from the fourth or fifth pharyngeal pouch provides parafollicular cells which secrete calcitonin.

The descent of the thyroid is marked by the thyroglossal duct which connects the gland to the foramen caecum. It is divided into suprahyoid and infrahyoid portions by the growth of the hyoid bone from the second and third pharyngeal arches. The duct usually atrophies but may persist as a fibrous cord or as a tube.⁸ Thyroglossal cysts may develop along its course, usually median in position (**Figures 65.19** and **65.20**), which move on swallowing and protrusion of the tongue.²⁹

A small or absent thyroid results in congenital cretinism (see Chapter 99, Branchial arch fistulae, thyroglossal duct anomalies and lymphangioma). Failure of normal descent may result in a lingual thyroid, causing dysphagia or it may be sublingual, prelaryngeal or suprasternal. Between the isthmus and hyoid bone a pyramidal lobe or a fibromuscular band, the levator glandulae thyroidea, may be found.⁶ The isthmus, or one lobe, may be absent.²⁹ More than half of abnormal neck masses are of thyroid origin.¹ Accessory thyroid tissue may be found in the neck, thymus, mediastinum, heart, trachea, oesophagus or liver, due to attachment to an adjacent organ and also, as part of a teratoid tumour, in the ovary.¹

EAR

The internal, middle and external ear each have a different origin.

© Hodder Arnold / Scott-Brown 7E

Figure 65.21 Diagram to represent the development of the otocyst from the otic placode, which in turn is derived from the ectoderm cranial to the first occipital somite. During the seven days of its development, the neural groove has also become converted into the future brain stem.

Each otocyst subsequently divides into a ventral part, which gives rise to the saccule and cochlear duct, and a dorsal part which forms the utricle, semicircular canals and endolymphatic duct (**Figure 65.22**). These epithelial derivatives are collectively termed the membranous labyrinth. Neural crest cells migrate away from the developing otocyst to form the statoacoustic ganglion from which the vestibulocochlear nerve is derived.²

The cochlear duct develops as an outpouching of the saccule and penetrates the surrounding mesenchyme in a spiral fashion forming 2.5 turns. The ductus reuniens connects the saccule and cochlea. This mesenchyme

Figure 65.22 Development of the membranous labyrinth from the otocyst. This rapid and complex change occurs over a six-week period.

differentiates into cartilage which then vacuolizes to form two perilymphatic spaces, the scala vestibuli and scala tympani, around the cochlear duct or scala media. The vestibular membrane separates the duct from the scala vestibuli, while the basilar membrane separates the duct from the scala tympani (**Figure 65.23**). An inner sulcus divides the epithelial cells of the cochlear duct into an inner ridge, the future spiral limbus, and an outer ridge. The outer ridge forms one row of inner and three to four rows of outer cells, separated by the tunnel of Corti. On either side of the tunnel, pillar cells give mechanical rigidity, while the sensory cells develop a cluster of

stereocilia and are termed hair cells. These are covered by the tectorial membrane which extends from the spiral limbus. The hair cells and tectorial membrane comprise the organ of Corti which transmits sensory impulses to the spiral ganglion and then, via the cochlear fibres of the vestibulocochlear (VIII) nerve, to the brain. Differentiation proceeds in the basal to apical direction as the duct elongates.

The dorsal part of the otocyst flattens and out-pouchings appear to form semicircular canals. The walls between adjacent canals resorb to give rise to three canals – superior, posterior and lateral – emerging from the utricle. One end of each canal dilates to form a crus ampullare in which a fibrogelatinous cupola develops. The crus nonampullare of the lateral canal persists, while those of the superior and posterior canals fuse to form the crus commune nonampullare. In each ampulla, sensory cells form a crest or crista ampullaris. Similar sensory areas, the maculae, develop in areas where vestibular fibres of the vestibulocochlear (VIII) nerve enter the walls of the utricle and saccule. Two cell types differentiate; sensory cells with a single kinocilium and many stereocilia and supporting cells which produce a gelatinous matrix and are responsible for the formation of otoconia.³⁰

Congenital malformations of the inner ear ranging from complete cochlear aplasia to incomplete partition of the cochlea, first described by Mondini in 1791, are reviewed by Graham *et al.*³¹

Middle ear

As the first pharyngeal pouch grows laterally to meet the floor of the first pharyngeal cleft, the ossicles and

tympanic branch of the facial (VII) nerve develop in mesenchyme between them. The proximal part of the pouch forms the narrow auditory or Eustachian tube, while its distal part widens to form the tubotympanic recess which gives rise to the primitive tympanic cavity. Cleft ectoderm, mesenchyme and pouch endoderm form the three layers of the future tympanic membrane, with the handle of the malleus embedded in it, traversed by the chorda tympani. The malleus and incus are derived from the first pharyngeal arch cartilage and begin to ossify at 16 weeks, reaching adult size and form by 25 weeks. The stapes is derived from the second arch (Reichert's) cartilage and begins to ossify at 18 weeks. The base of the stapes appears in the lateral wall of the otic capsule, surrounding the otocyst, where it occupies the oval window, and hence may be involved in otosclerosis. Rarely the stapedia artery, passing between the crura, may persist. The ossicular ligaments develop within endodermal reflections connecting the ossicles to the walls of the tympanic cavity. The tensor tympani, attached to the malleus, and stapedius, attached to the stapes, are supplied by the mandibular and facial nerves, respectively. The middle ear reaches adult size before birth.¹ Epithelium of the tubotympanic recess invades the mastoid process to form the antrum and, postnatally, the mastoid air cells.

Type 1 malformations of the middle ear are due to abnormal development of the ring surrounding the tympanic membrane. In type 2 malformations, the space between the mandibular fossa and the front of the mastoid process is absent, resulting in an abnormal course of the facial (VII) nerve which may be associated with cochlear malformations.^{1,31} Evolutionary and mechanical influences on middle ear development are discussed by Prendergast.³²

Temporal bone

The temporal bone is composed of four parts: petromastoid, styloid, squamous and tympanic.⁴ The petromastoid originates from the capsule surrounding the otocyst and progresses from mesenchyme to cartilage to bone. It gives rise to the petrous which encloses the bony labyrinth, the tegmen tympani which roofs the tympanic cavity, and forms the mastoid process at one to two years after birth. The styloid process is derived from the second pharyngeal arch cartilage. The squamous part ossifies intramembranously and includes the mandibular fossa and zygomatic process. The tympanic part may be derived from the first pharyngeal arch and develops as an incomplete bony ring which unites with the squamous part before birth at the squamotympanic fissure.¹ The tegmen separates them in part and first arch derivatives pass through the petrotympanic fissure to the spine of the sphenoid and then, as the sphenomandibular ligament, to the lingula of the mandible.

External ear

The external auditory meatus develops from the dorsal portion of the first pharyngeal cleft and canalizes from medial to lateral. Epithelial cells proliferate to form a meatal plug which may persist after birth causing conductive deafness. Auricular hillocks, three from the first and three from the second pharyngeal arch, surround the cleft below the level of the mandible. As they ascend, some mandibular hillocks contribute to the tragus, while the remainder form the bulk of the auricle (**Figure 65.24**), but abnormalities such as auricular appendages and fistulae are common (**Figure 65.25**). Congenital malformations of the ear are often features of common chromosomal syndromes, such as Trisomy 18, Trisomy 21, Fragile X and Treacher Collins syndrome.²

© Hodder Arnold / Scott-Brown 7E

Figure 65.24 Early stages in the development of the auricle. Six cartilaginous hillocks are visible around the first pharyngeal groove. During subsequent development these become the cartilage of the auricle, although the bulk of the auricle appears to be derived from the cartilage of the second arch.

Figure 65.25 Accessory auricle in an infant.

KEY POINTS

- Major organ systems are established during the embryonic period, weeks 3–8.
- Pharyngeal arch, pouch and cleft development explain motor and sensory innervations and common abnormalities.
- Palatogenesis explains most craniofacial clefting.
- Recent advances in laryngeal embryology correlate well with clinical data.
- Thyroglossal duct cysts are the most common congenital cervical abnormality.
- Ear abnormalities are commonly associated with chromosomal syndromes.

Deficiencies in current knowledge and areas for further research

Morphological descriptions of embryological development are well established.^{2, 9, 15, 17, 18, 27, 28, 29, 30} The underlying genetic and molecular mechanisms are now beginning to be understood.^{5, 10, 12, 19} Detection of molecular markers may lead to earlier and more effective intervention while increased understanding of mesenchymal stem cell and matrix interactions offer the prospect of tissue engineered replacement surgery within the next five years. By clearly understanding the mechanisms by which organs develop, the effects of teratogens may be predicted and birth defects avoided.

ACKNOWLEDGEMENTS

I would like to thank my colleagues, Professor EJ Guiney, Professor MJ Ryan and Professor BE McCartan, for providing illustrations and for their helpful comments on the text.

INTRODUCTION

Table 66.1 provides a glossary of terms used in genetics.

Types of deafness

Deafness is a common childhood problem. Serious hearing impairment is found in one in 800 newborns.¹ Abnormal genetic make up accounts for approximately 50 percent of permanent childhood deafness.² In addition, several genes have been found that, when mutated, either cause or predispose to progressive hearing loss,³ suggesting that this type of deafness may also have a significant genetic basis. Genetic deafness, therefore, poses a problem both at birth and later in life. It is therefore important to identify the mutated genes involved and to understand the ear pathology caused by these defective genes.

Deafness can be broadly categorized into **syndromic** (deafness associated with other symptoms) or **nonsyndromic** (deafness associated with no other symptoms). Many more loci have been found for syndromic deafness

than nonsyndromic deafness, despite the fact that these make up the minority of all inherited deafness cases (about 30 percent of deafness is thought to be syndromic). This is likely due to the fact that syndromic cases of deafness are more accurately diagnosed due to the additional features of the syndromes.

Nonsyndromic types of deafness are classified on the basis of the mode of inheritance as follows: DFNA (autosomal dominant), DFNB (autosomal recessive) and DFN (X-linked forms). At present, 39 DFNB, 51 DFNA, eight DFN, one modifier DFNM1⁴ and two mitochondrial loci (regions on the mitochondrial chromosome) have been identified,⁵ and 36 causative genes have been reported (Table 66.2).^{5,6}

Clinically, deafness is generally categorized on the basis of which auditory structures are affected. Conductive deafness refers to defects found in the outer or middle ear, whereas sensorineural hearing loss (SNHL) refers to disruptions in the sound transmission from the inner ear to the cortex of the brain. Most SNHL is due to abnormalities at the level of the inner ear. Inner ear pathology is further categorized into three groups: **morphogenetic**, **cochleosaccular** and **neuroepithelial**.⁷

Table 66.1 Glossary of terms used in genetics.

Term	Name	Explanation
Autosomal dominant gene	DFNA	A single, abnormal gene on one of the autosomal chromosomes (one of the first 22 'non-sex' chromosomes) from either parent can cause certain diseases. One of the parents will usually have the disease (since it is dominant) in this mode of inheritance. Only one parent must have an abnormal gene in order for the child to inherit the disease.
Autosomal recessive gene	DFNB	An abnormal gene on one of the autosomal chromosomes (one of the first 22 'non-sex' chromosomes) from each parent is required to cause the disease. People with only one abnormal gene in the gene pair are called carriers, but since the gene is recessive they do not exhibit the disease. The normal gene of the pair can supply the function of the gene so that the abnormal gene is described as acting in a recessive manner. Both parents must be carriers in order for a child to have symptoms of the disease; a child who inherits the gene from one parent will be a carrier.
Genotype		The genetic composition of an organism
Genetic 'mapping'		Technique employed to identify gene by using primers (manufactured genetic markers)
Gene transfer		Transfer of certain genes using vectors, such as viruses
Linkage analysis		Similar technique to genetic mapping in gene identification by using primers
Locus		A region on a chromosome
Modifier genes	DFNM1	Genes that do not cause disease but have the ability to influence the expression of other genes resulting in abnormalities
Mutation		Abnormalities caused by alteration of genome
Phenotype		The physical appearance of an organism
Transfer 'vector'		A carrier employed to enter and introduce genetic materials into a cell, e.g. a virus
Transgenesis		The insertion or deletion of a gene at the embryonic stage of development resulting in different phenotypes
X-linked	DFN	Genes that can only be inherited from the maternal side, e.g. mitochondrial genes

Morphogenetic defects, characterized by abnormal development of the ear leading to a malformation, only occur in 15–20 percent of profoundly deaf humans.⁸ This is because important morphogenetic genes are often involved in diverse development processes and mutations in these genes are likely to lead to antenatal death. Cochleosaccular refers to abnormalities in the stria vascularis, which regulates the ionic balance of the endolymph. The third and probably the most common type of inner ear pathology, neuroepithelial, is caused by defects in the organ of Corti, in which the hair cells responsible for the first step of the pathway of transducing sound information to neural code are situated.⁸

Using mouse mutants in understanding human genetic deafness

Identifying the gene that causes a particular type of deafness involves, first of all, localizing the mutation to a specific region of a chromosome (genetic mapping). In human populations, this process is confused by the fact that many types of deafness, particularly nonsyndromic forms, are difficult to diagnose as there are few defining features. To minimize grouping cases of deafness together in which the causative gene may be different, genetic

mapping must be done either in large consanguineous families or in populations that have been isolated from immigration.⁹ To a certain degree, this approach has been successful in that researchers have been able to localize over 100 nonsyndromic forms of deafness.⁵ However, the step between localizing the gene to a region of the chromosome and actually identifying the mutated gene is a large and difficult one.

The mouse appears to be the best model for understanding genetic hearing and balance defects in humans for several reasons. Firstly, because large numbers of mice which all carry the same mutation can be produced, the region of the chromosome in which the mutation is located can be more specifically pinpointed than in humans, making the mouse a powerful tool for gene identification. Due to genomic conservation between mice and humans, the mutated genes can be positioned and identified in the mouse and the homologous human genes can be identified and sequenced for possible mutations. Secondly, the mouse cochlea is structurally very similar to humans in its organization and specialization. Both species have similar types of inner ear pathology, and in some cases, the orthologous (same gene, but different species) gene is involved in deafness in the two species. Thirdly, there have been recent advances in the manipulation of the mouse genome, such that it is the most appropriate vertebrate in which to perform

Table 66.2 Human syndromes with known causative genes.

Syndromes	Causative genes	Clinical features
Alport syndrome	COL4A5, COL4A3, COL4A4	Nephritis, hearing loss, lenticonus and other eye disorders, immunologic abnormality of skin, disorders of platelets, abnormalities of white blood cells, or smooth muscle tumours
Branchio-oto-renal syndrome	EYA1	Auricular pits/fistulae, blocked/absent nasolacrimal duct, branchial cleft/sinus/cysts, cleft palate, cochlear/saccular abnormalities, deafness, double ureters, facial weakness, hydronephrosis, microphthalmia, atretic auditory canal, renal agenesis/dysplasia or ectopic kidneys
Norrie syndrome	Norrin	Pseudotumour of the retina, retinal hyperplasia, hypoplasia and necrosis of the inner layer of the retina, cataracts, phthisis bulbi, progressive sensorineural hearing loss and mental disturbance
Pendred syndrome	SLC26A4	Goitre, hypothyroidism, deafness
Stickler syndrome	COL2A1, COL11A2, COL11A1	Progressive myopia, vitreoretinal degeneration, premature joint degeneration with abnormal epiphyseal development, midface hypoplasia, irregularities of the vertebral bodies, cleft palate deformity and variable sensorineural hearing loss
Treacher Collins syndrome	TCOF1	Coloboma of the lower eyelid (the upper eyelid is involved in Goldenhar syndrome), micrognathia, microtia, hypoplasia of the zygomatic arches, macrostomia and inferior displacement of the lateral canthi
Usher syndrome	MYO7A, USH1C, CDH23, PCDH15, USH2A, USH3	Hearing impairment and retinitis pigmentosa – there are at least three clinical subtypes
Pfeiffer syndrome, Kallmann syndrome, craniosynostosis	FGFR1	Craniosynostosis, ocular proptosis, mixed deafness, mid-face dysgenesis
Waardenburg syndrome	PAX3, MITF, SLUG, EDNRB, EDN3, SOX10	Dystopia canthorum (lateral displacement of the inner canthus of each eye), pigmentary abnormalities of hair, iris and skin (often white forelock and heterochromia iridis), sensorineural deafness
Jervell and Lange-Nielson	<i>KVLQT1</i> , <i>KCNE1</i> (<i>IsK</i>)	Long QT syndrome and deafness
Maternally inherited diabetes and deafness (MIDD)	<i>tRNA^{Leu}</i> , <i>tRNA^{Lys}</i> , <i>tRNA^{Glu}</i>	Deafness, diabetes, seizures, migraines, short stature, mental retardation and stroke-like episodes
Mitochondrial encephalopathy, lactic acidosis and stroke-like episodes (MELAS)	<i>tRNA^{Leu}</i>	Deafness, mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes.
Myoclonic epilepsy and ragged red fibres (MERRF)	<i>tRNA^{Lys}</i> , <i>tRNA^{Leu}</i>	Deafness, myoclonus, ataxia, progressive external ophthalmoplegia and seizures
Kearns-Sayre syndrome (KSS)	Several <i>tRNA</i> genes	Weakness of facial, pharyngeal, trunk and extremity muscles, deafness, small stature, electroencephalographic changes, markedly increased cerebrospinal fluid proteinophthalmoplegia, pigmentary degeneration of the retina and cardiomyopathy
Progressive myoclonic epilepsy, ataxia and deafness	<i>tRNA^{Ser}</i>	Deafness, ataxia and seizures

Modified from Ref. 5.

transgenesis, a feature which can be useful in both the identification of a mutated gene as well as in the production of potential mouse models. Finally, the mouse is useful in embryological and developmental studies, and invasive physiological tests can also be performed in anaesthetized mice, which provide important clues to the basis of the dysfunction and could not be carried out in humans.

THE DEVELOPMENT OF THE EAR

The branchial apparatus

In the fourth and fifth week of development in the human embryo, five ridges develop in the side walls of the primitive pharynx (**Figure 66.1**). These ridges are known as branchial arches. Initially they consist of a mesodermal

Figure 66.1 Coronal section through the developing pharynx. The branchial arches are numbered 1, 2, 3, 4, 6. Redrawn from Ref. 10, with permission.

core surrounded by epithelium of endodermal and epidermal origin. These arches are separated by deep grooves, known as branchial clefts. At the same time as the development of the arches and clefts, a number of outpocketings known as the branchial pouches appear on the lateral wall of the pharynx. These pouches gradually penetrate the surrounding mesenchyme, but do not establish an open communication with the exterior. The mesodermal core of the branchial arches is pleuripotent in that it can give rise to any number of structures, for example cartilage, muscles or arteries. The development of the branchial apparatus is covered in Chapter 65, Head and neck embryology. Those features pertinent to the development of the ear are reviewed here.

The outer ear

The pinna of the outer ear is formed by a gradual alteration and partial fusion of the first and second branchial arches, which include arch ectoderm and mesoderm (**Figure 66.1**). The groove between the two arches deepens and gives rise to the external acoustic canal (EAC). The development of the outer ear is hence controlled, in part, by genes that determine the identity of the first and second arches. This regulation is mediated through the segmentation of the developing hindbrain into **rhombomeres**. The hindbrain is the source of the neural crest cells that populate the branchial arches. Mutations in the genes that control the development of the fourth segment of the hindbrain, rhombomere 4, can cause abnormalities of the outer ear.¹¹ These genes include *Hoxa1*,¹² *Hoxb1*,¹³ goosecoid (*Gsc*)^{14, 15} and genes for the secreted peptide, endothelin 1 and its related molecules.^{16, 17, 18, 19}

The middle ear

The embryological origins of the middle ear are diverse. Middle-ear morphogenesis can be altered under various conditions that cause congenital abnormalities in head development. Genes that are expressed in the first and second branchial arches and in the hindbrain segments that give rise to these arches, appear to have a significant role in patterning the middle ear. These include *Gsc*,^{14, 15} *Dlx2*,²⁰ retinoic acid receptors (*Rars*),²¹ *Prx1*,²² *Otx2*,²³ *Hoxa1*,¹² *Hoxb1*¹³ and endothelin-related molecules.¹⁶

The tympanic membrane is formed by the apposition of two epithelia provided by the EAC and the middle ear cavity, with a fibrous layer between them. Embryologically, the epithelia of the EAC and middle ear cavity derive from the ectoderm of the first branchial cleft and the endoderm of the corresponding branchial pouch respectively (**Figure 66.1**). The fibrous layer originates from the branchial arch mesenchyme.²⁴ A functional tympanic membrane is formed via successive reciprocal interactions between the branchial arch mesenchyme and the overlying epithelia, and one of the main steps is the insertion of the handle of the malleus into the tympanic membrane. A central role of this process is played by the tympanic ring, which is a C-shaped membranous bone that develops from midbrain and rhombomere 1 neural crest and provides physical support to the tympanic membrane.²⁵

Ossicles are developed from the mesenchyme of the proximal area of the branchial arches. The malleus, originating from the midbrain and rhombomeres 1 and 2 crest cells, and the incus, originating from rhombomeres 1 and 2 crest cells, both derive from the first branchial arch. The second branchial arch element of the middle ear, the stapes, derives from rhombomere 4.²⁵ The ossicles are derivatives of the neural crest. Proper development of the branchial arches, and thus the ossicles, depends on information provided by the neural crest, the mesoderm, and the overlying epithelia. The vertebrate ear develops from a complex convergence of tissues from all three germ layers (endoderm, mesoderm and ectoderm), as well as the neural crest. A major contribution to the outer ear is made from the first and second branchial arches, which include the arch ectoderm and mesoderm. The middle ear is formed from cells arising from the neural crest and paraxial mesodermal cells that initially migrated to the branchial arches and then coalesced to form the middle ear components. It also contains contributions from the endoderm, as it is lined by mucosal tissue that expands into the middle ear from the oral cavity. Embryologically, this is derived from the first branchial pouch. The epithelial tissues and neurons of the inner ear are formed of placodal ectoderm, which invaginates to form the otocyst, a cartilaginous capsule that eventually ossifies and surrounds the epithelial core of the inner ear. Most of the otic capsule is derived from paraxial mesoderm, and forms through epithelial–mesenchymal interactions with

the membranous labyrinth that surrounds and protects (Figure 66.2). Several molecules including endothelin 1, Fgf8 and retinoic acid (RA) have been shown to play specific signalling roles in the development of the branchial arches and middle ear structures.²⁶

The timing of the migration of neural crest cells that will form each of the different middle ear components follows a typical sequence. The first neural crest cells to migrate are those contributing to the head of the malleus, followed by those forming the head of incus. The next to migrate are rhombomere 4 crest cells contributing to the stapedial footplate. The crest cells that make the tympanic ring and the handle of malleus start their migrations shortly after. This is then followed by the migration of crest cells that form the stapedial arch and those contributing to the neck of the malleus. The last cells to migrate are those that form the long process of the incus.²⁵

The process involves more than just the formation of individual components. These have to be connected in a normal and orderly fashion, so that the middle ear can function properly. The insertion of the handle of the malleus between the two epithelial layers of the tympanic membrane relies on the proper formation of the EAC. The handle of the malleus can be formed even in the

absence of most of the malleus, provided that the EAC is present. On the medial side of the ossicular chain, the formations of the stapes and the oval window appear to be controlled by the *Hoxa2* gene;²⁷ the insertion of the stapes into the oval window seems to be regulated by the *Pou3f4* gene.²⁸

The inner ear

During embryonic development, the inner ear arises from a simple epithelium adjacent to the hindbrain, the **otic placode**, that is formed through inductive interactions with surrounding tissues. The otic placode, which is a thickened area of ectoderm next to the hindbrain rhombomeres 5 and 6 in 8–10 somite embryos, invaginates to form the otic cup, an ellipsoid-shaped structure lined by a pseudostratified epithelium. The cochlear and vestibular neurons are formed by delamination from the otic cup. Initially, they form a single structure, the cochleovestibular ganglion, which divides into the cochlear and vestibular ganglia as development proceeds. The otic cup then ‘pinches off’ to form a hollow ball of cells called the otic vesicle (otocyst) (Figure 66.2). The inner ear then enlarges, while undergoing complex changes, in order to assume its final morphology.

Hindbrain segmentation occurs at the same time that the otic placode arises and the hindbrain could be crucial for otic placode specification. By the time the otocyst that is adjacent to rhombomere 5 has formed, hindbrain segmentation is complete. At this time, neural crest cells migrate out of the hindbrain and stream around the adjacent otocyst as they descend ventrally to form the branchial arches, together with their surrounding mesodermal cells, providing information transfer from neural ectoderm to the otic field.¹¹

The otic vesicle (otocyst) enters an early proliferation phase followed by a differentiation phase, during which morphogenesis and patterned development of specific cell types occurs. Basic processes in the development of the otic vesicle have been shown to include the initiation and completion of each of the following overlapping steps.²⁹

- **Placodal competence** is when the prospective placodal ectodermal stripe is able to develop into any placode derivatives, if placed in the adequate position.
- **Specification** of the otic field then enables the placodally competent ectoderm to be restricted to the prospective ear region.
- **Determination** occurs when the otic field progressively acquires its identity and becomes committed to its otic fate.
- Regional and cell-fate specification of the otic vesicle may be related to the earliest stage of regional gene expression and to the first events of **cell differentiation**, respectively.

Structurally in mice, the cochlear duct develops from a tubular out-pocketing of the ventral portion of the otocyst on embryonic day 11 (E11) and starts to coil. By embryonic day 17 (E17), it attains its mature shape of one and three-quarters turns. The organ of Corti develops from the thickened epithelial cells of the cochlear duct. This thickened area is formed of tall columnar cell mounds: the lesser and the greater epithelial ridges. It is believed that inner hair cells (IHC) derive from the greater epithelial ridge and the outer hair cells (OHC) derive from the lesser ridge. *Pax2* has been shown to be responsible for the outgrowth of the cochlea.

The main events of semicircular canal formation in a developing mouse occur between 11.5 and 13 days embryonically (E11.5–E13). From the medial aspect of the otocyst, an uncoiled tube grows out and projects dorsally. The first two semicircular canals to form, the superior and the posterior, develop from a shared pocket-shaped rudiment. This out-pocketing begins to develop from the dorsal part of the otocyst by E11.5 and shows the first signs of conversion into a pair of semicircular canals. The canals are formed by fusion of the lateral and medial epithelial surfaces of the out-pocketing and the subsequent disappearance of the fused region of epithelia. The superior canal forms first, followed closely by the posterior; the horizontal canal forms last from a separate rudiment. By E13, all the major changes that

the inner ear undergoes are complete and the inner ear labyrinth resembles a miniature replica of its adult form.³⁰ The utricle and its macula are derived from the upper middle third of the medial and lateral walls of the otocyst. The saccule and its macula are derived from the lower middle third of the medial wall of the otocyst (Figure 66.3).

Origin of the sensory organs

The inner ear houses the receptor cells for two distinct sensory pathways: the auditory and vestibular systems. Patterning of the inner ear into prospective auditory and vestibular sensory areas is associated with restricted gene expression domains during the stages of development from otic placode to otocyst. Ventromedial areas, where the putative auditory epithelium forms, express *Pax2*, *Dlx4*, *Fgf2*, *Fgf3*, *BMP4*, *notch* and *Ncam* genes. Dorsolateral areas which form vestibular epithelium express *Hmx2*, *Hmx3*, *Dlx3*, *MshC*, *MshD*, *Sox9*, *p75*, *Lmx1*, *Gbx3*, *Sek1*, *BMP7* and *Igf1* genes.³¹

Once the sensory hair cells have been specified, their continued differentiation requires transcription factor *Pou4f3*. In the absence of this gene, the hair cell phenotype aborts at an early stage, eventually leading to the death of hair cells and the supporting cells.³²

Figure 66.3 Schematic transected diagrams of inner ear morphogenesis during the period of semicircular canal development (left inner ear). (a) The walls of the canal plate have met in the region of the superior semicircular canal (arrow). (b) The fused layer of canal plate epithelium in the region of the superior canal has now disappeared (arrow), during which time the posterior canal walls have come together and are now apposed (asterisk). (c) All fused regions of superior and posterior canal plate have now disappeared leaving two canal tubes that are united centrally by the crus commune. A, anterior; C, cochlea; CC, crus commune; E, endolymphatic duct; H, horizontal; L, lateral; M, medial; P, posterior; SA, saccule; S, superior; U, utricle. Modifier genes affecting the development of the auditory system

More often than not, a given genetic disorder may manifest in a variety of ways. Variable phenotypes can result from genetic modifier loci. Modifier genes affect the phenotypic outcome of a given genotype by interacting in the same or parallel biological pathway as a disease gene. The effect can be enhancing, leading to a more severe mutant phenotype, or suppressive, reducing the mutant phenotype even to the extent of completely restoring the normal condition. Modifier genes can also alter the clinical presentations of a given disease, resulting in different combinations of traits. Moreover, multiple modifier genes may act in combination to create a cumulative effect on the expression of a phenotype. Human modifiers of hearing include *DFNM1* locus which suppresses hearing loss among individuals with *DFNB26* mutation⁴ and a locus on chromosome 8, which modifies maternally inherited aminoglycoside-induced deafness associated with a mutation (*A1555G*) in the mitochondrial 12S ribosome RNA.³³

RECENT ADVANCES IN GENETIC MANIPULATION IN THE TREATMENT OF CONGENITAL DEAFNESS

The purpose of any medical research is to apply the findings to clinical use. It may one day be possible to reverse certain types of defect that affect the early development of the auditory and vestibular systems. A prerequisite for treatment will almost certainly be early and accurate diagnosis. Screening programmes can then be established using molecular techniques. Groups with strong family histories of vestibular disorders and/or deafness with any related syndromes and premature newborns should be targeted for screening in the first instance. Molecular techniques can scan for the genetic defect at several levels. They may be used in linkage analysis, where the location of the gene on a particular chromosome is identified; or the techniques may identify the actual gene, the mutation within the gene and the gene product.³⁴

Some childhood hearing loss may be progressive during the first few months or years of life. Early diagnosis of hearing impairment in children would be essential if medical or surgical interventions were to stand a good chance of preserving some hearing ability. Intervention would depend on us having a much greater understanding of the likelihood of developing a serious hearing impairment than we presently have, so that a realistic prognosis could be provided to aid a family's decision.³⁵

Gene transfer

The prospect of therapeutic insertion of genetic material into the inner ear promises to be an attractive technology

for clinical applications. It offers the hope of preventing, arresting, reversing or curing vestibular or hearing disorders caused by hereditary diseases or environmental insults. There are currently very few treatment options for vestibular disorders and sensorineural hearing loss and, therefore, it is important to investigate and develop new technologies for inner ear disease. *In utero* gene transfer may indeed be an option, but this technology will have many technical and ethical issues that remain to be overcome.

A number of different gene transfer vectors have been studied *in vivo* for their efficacy, utility and safety in intracochlear gene transfer. Vectors successfully studied include cationic liposomes, adeno-associated virus, adenovirus, lentivirus, herpes simplex virus and vaccinia virus, with variable intensities of transgene expression in different parts of the organ of Corti.³⁶

For experimental purposes as well as future clinical application, it is important to develop a vector delivery system that preserves hearing and vestibular functions, as well as inner ear architecture. Systemic administration of the vectors has the disadvantage of systemic toxicity including viral hepatitis and encephalitis.³⁷ Direct instillation, on the other hand, allows high vector concentration to be delivered to the target organ, using a small amount of vector solution, which increases the likelihood of gene delivery to the targeted tissue, while minimizing leakage of the vector to the surrounding organs. Several techniques of intracochlear vector delivery have been developed and their efficacy and safety have been compared and contrasted.³⁶ They include miniosmotic pump infusion or microinjection into the scala tympani via the round window, infusion or microinjection into the scala tympani through a cochleostomy, injection into the endolymphatic sac accessed from the posterior fossa and gel foam application to the round window membrane. The first three methods have the advantage of a controlled steady intracochlear perfusion, but have the disadvantage of potentially physically damaging the architecture of the cochlea. Gel-foam soaked with the vector solution applied to the round window is noninvasive and nondestructive, and does not cause disruption to the anatomy of the inner ear.³⁶ However, the exact mechanism of vector transfer through the round window membrane is poorly understood and hence there is no control over the rate of delivery. It has also been shown that transgene expression in the contralateral, noninjected cochlea occurs, suggesting that systemic dissemination could potentially be associated with direct delivery methods. Three potential routes of spread from the cochlea have been suggested and they include viral spread via the cochlear aqueduct which connects the scala tympani of the basal turn of the cochlea to the cerebrospinal fluid (CSF) space, transmission of vectors through the temporal bone marrow spaces and haematogenous dissemination.³⁸ To date, there has been no report of gene transfer being used to successfully treat deafness in an animal model.

Stem cell and gene therapy

In addition to single gene transfer, there has been great interest in the potential of the twin technologies of stem cell and gene therapy for medicine. Hair cells in the cochlea are very vulnerable to disruption of their homeostasis and tend to die if they cannot function normally.³⁹ Once dead, hair cells are not naturally replaced. One approach to treating deafness could be to trigger regeneration of cochlear hair cells. However, there is no point in stimulating the regeneration of hair cells that are unable to function because of a genetic defect. Accurate diagnosis combined with dual treatment of stem cell insertion and gene transfer would be vital for this approach to succeed. Over recent times, the potential of somatic stem cells for therapeutic applications has become almost infinite, limited only by the ingenuity of investigators in the manipulation of their genomes and culture conditions.⁴⁰

Cochlear gene transfer can offer several potential applications including the study of specific expression and function of certain genes and the delivery of therapeutic agents. However, demonstration of transgene expression in tissues outside the treated cochlea raises concerns about the safety of its application regarding systemic dissemination of the vectors used.³⁶ Better techniques to improve and enhance specific vector delivery into the cochlea need to be developed and tested.

Timing of intervention

In humans, the otic placode starts to develop when the embryo has reached the seventh somite stage (about 22 days) and by 25 weeks, the development of the organ of Corti and the vestibular system are complete and resemble the adult form. Prenatal tests for congenital abnormalities including Down syndrome, cystic fibrosis and spina bifida are performed by the end of the first trimester and it would be too late if interventions were to be implemented to the developing ear at this stage. The rudimentary pinna has formed by 60 days and in the fourth month convolutions have attained their adult form, although further enlargement continues during the remaining months of gestation and also in the post-natal period.⁴¹ Timing of genetic intervention would therefore be important. Direct gene transfer or stem cell insertion into the inner ear at the embryonic stage would involve some form of intrauterine surgery and surgical intervention on the human foetus has been performed for more than two decades in the United States.⁴² In the past, only foetuses with life-threatening defects, for example, giant foetal cervical teratoma⁴³ have been considered as candidates for prenatal correction. However, more foetal surgical procedures are now being performed for non-lethal conditions, such as congenital diaphragmatic hernia

using fetoscopic repair techniques.⁴² Surgical intervention involving inner ear gene transfer on human embryos seems a good idea, but is still rather far-fetched with the technology available to us at present. It may be more feasible to treat post-natal progressive deafness and/or vestibular disorders by using this approach, but the exact pattern of expression and functions of the genes involved must be understood prior to such intervention. In addition, the attitudes of the patients and their families and their views on such intervention must be respected. The deaf community in the United Kingdom is very advanced, with its own culture and there has been anecdotal evidence that deaf couples do not necessarily want their children to be able to hear if it means that they will be excluded from the deaf community to which their parents belong (see Chapter 69, Investigation and management of the deaf child).

Drug therapy

An alternative approach is based on drugs, which, by definition, are small molecules with ready access to the target cells. We may be able to exploit alternative pathways to carry out the task that is affected by a mutation. For example, connexin 26 mutation is thought to be the most common cause of nonsyndromic deafness in the Caucasian population. Another connexin may be capable of substituting for connexin 26 in forming gap junctions, but its gene may not normally be expressed in the cochlea. A drug might therefore be developed to activate expression of the alternative connexin gene in the cells needing to form gap junctions. Clues about which alternative pathways might be worth exploiting will come from investigations of interacting genes.³⁵

KEY POINTS

- Congenital deafness is a common childhood problem.
- Genetic abnormalities cause not only congenital deafness; several genes have been found that, when mutated, either cause or predispose to progressive hearing loss.
- Mice appear to be the best model for the study of genetic deafness.
- Understanding the molecular biology of the auditory system may be the key to the future development of genetic counselling and treatment for congenital deafness.
- Surgical intervention involving inner ear gene transfer on human embryos seems a good idea, but is still rather far-fetched with the technology currently available.

Deficiencies in current knowledge and areas for future research

Genetic testing for deafness is now a reality and has changed the paradigm for evaluating deaf patients. It will be used by surgeons for diagnostic purposes and as a basis for treatment and management options. Mutation screening is currently available for only a limited number of genes, such as connexin 26. In these cases, diagnosis, carrier detection and reproductive risk counselling can be provided. In the future, there will be an expansion of the role of genetic testing and counselling will not be limited to reproductive planning. Treatment and management decisions will be made based on specific genetic diagnoses. New discoveries and technologies will expand and increase the complexity of genetic testing options. Otolaryngologists will therefore have to familiarize themselves with current discoveries and accepted protocols for genetic testing.

SEARCH STRATEGY

The data in this chapter are supported by a Medline and CINAHL search for relevant articles published in English, using key words infant or newborn and hearing screening and hearing loss.

INTRODUCTION

Any discussion of screening must be firmly grounded in an understanding of the principles of screening as a public health exercise, an understanding of some of the key evidence regarding the epidemiology of the condition of interest, in this case childhood hearing loss, and the evidence for or against different approaches to screening and surveillance for that condition. Thus, this chapter starts with an outline of the key definitions and principles of screening, before proceeding to review evidence on the prevalence of different types of childhood hearing loss. The case for newborn screening is summarized and evidence for current performance of newborn screens reviewed. Other approaches to screening and surveillance in the preschool years are also reviewed (the eight-month screen, the school entry screen) and the position with regard to temporary childhood hearing loss discussed.

PRINCIPLES AND DEFINITIONS

Surveillance is a process of ongoing or regular observation of the health of individuals or populations. Traditionally health service professionals have considered surveillance essentially as secondary prevention through early detection. However, the concept that child health depends upon continuous vigilance and supervision by health professionals is fairly narrow and supervisory; child health surveillance is now regarded as just one component of child health promotion programmes which aim to promote partnership between parents, children and health professionals, in which parents are empowered to make use of services and expertise according to their needs.

Screening is a public health activity in which members of a defined population, who do not show any obvious symptoms, are offered a test in order to identify those individuals who are more likely to be helped than harmed

by further assessment or treatment to diminish the risk of a disease (or impairment) or its complications (or consequences). Accurate early diagnosis of serious conditions offers the opportunity to initiate treatment before the disease progresses (or to intervene to mitigate the consequences of the impairment). When screening is done well, it can be very beneficial.

Even though screening can potentially help to save lives or improve the quality of life through early diagnosis of serious conditions, it is not an infallible process. Screening can potentially reduce the risk of developing a disease (or impairment) or its complications (or consequences). However, in all screening programmes there are inevitably individuals who are referred as having the condition but do not (**false positives**), and who are not referred but do have the condition (**false negatives**).

From an ethical viewpoint, screening differs from responsive clinical practice, since screening is targeting individuals who appear healthy and is offering to help individuals make an informed choice about their health or the health of their children. It is particularly important for individuals who consent to be screened or have their child screened to be aware of the risks involved and have reasonable expectations of a screening programme.

In the UK, the National Screening Committee 'assesses proposed new screening programmes against a set of internationally recognised criteria covering the condition, the test, the treatment options and the effectiveness and acceptability of the screening programme. Assessing programmes in this way is intended to ensure that they are more beneficial than harmful, and can be implemented at reasonable cost. When research has shown screening to be effective in reducing mortality and morbidity from a particular condition, the National Screening Committee may decide to pilot the proposed screening programme. This provides valuable information on the effectiveness, feasibility and public acceptability of screening when performed in an ordinary health service setting rather than a specialist research site. Pilot studies enable informed decisions to be made about policy priorities; ensuring resources are targeted on services that are proven to work'.¹

The principles that a screening programme should satisfy have been identified in seminal work by Wilson and Junger.² These were extended by Haggard and Hughes³ in their review of screening for hearing loss in children.

- The condition (hearing impairment) should be an important health problem.
- There should be an accepted treatment, i.e. an acceptable means of habilitation for those identified by the screen.
- Facilities for assessment, diagnosis and treatment should be available.
- The hearing impairment should be recognizable at an early stage.

- There should be a suitable test for use as the screen.
- The test should be acceptable to the parents and to the child.
- The natural history of the condition should be known and understood.
- There should be an agreed policy on who to treat.
- The cost of case finding (including all consequential costs of the screening programme) should not be disproportionate to overall healthcare costs of care for the hearing-impaired child.
- Case finding should be seen as a continuing process.
- The incidental harm should be small compared to the overall benefits.
- There should be guidelines on how to explain results to parents with appropriate support.
- All hearing screening arrangements should be reviewed in the light of changes in demography, epidemiology and other factors.
- Cost and effectiveness of hearing screening should be examined on a case-type basis to maximize the effectiveness and benefit for each type before considering overall costs, effectiveness and benefits.

There are a number of key definitions relevant to screening programmes which should be used in the quality assurance and audit of any screening programme:

Coverage is the proportion of the target population who undergo the screen.

Screen positive result is a screening result that is greater than or equal to a specified cut-off level. In the case of permanent childhood hearing impairment, there is debate about the appropriate cut-off level; at present in the UK the cut-off level is the estimated hearing threshold (averaged across 0.5, 1, 2 and 4 kHz) of 40 dB HL. This level is based upon evidence for the benefits of early intervention in moderate or greater hearing loss. Further research on the effects of and early intervention for mild hearing loss in the 20–40 dB HL range is ongoing. A true-positive is an individual with a screen-positive result who has the condition (impairment). A false-positive is an individual with a screen-positive result who does not have the target condition (impairment).

Screen negative result is a screening result that is less than the specified cut-off level. A true-negative is an individual with a screen-negative result who does not have the condition (impairment). A false-negative is an individual with a screen-negative result who does in fact have the condition (impairment). Effective screening programmes attempt to reduce false-negatives to the irreducible minimum, while keeping false-positives within manageable service levels. The aim of a screen is to refer on a manageable proportion of the population for further (diagnostic) tests, that proportion being likely to contain as many of the true cases in the population as possible.

Sensitivity is the rate of true-positives or the proportion of individuals with the target condition in

the population who are correctly identified by the screen. The term can be applied to a screening test, if (as is the case with newborn hearing screening) the screen consists of more than one test, or to the screen as a whole, or indeed to the screening programme. **Test sensitivity** is the proportion of individuals who were given the test, have the condition (impairment) and were detected by the test. **Screen sensitivity** is the proportion of individuals who completed the screen who have the condition (impairment) and who were detected by the screen (which may consist of more than one test with conditional pass/refer rules). **Programme sensitivity** is the proportion of the subjects in the whole population with the specified condition (impairment) who are detected by the screening programme. It is a product of the screen sensitivity and the coverage achieved by the screen programme.

Specificity is the rate of true-negatives or the proportion of individuals free of the target condition in the population who are correctly identified as such by the screen. As with sensitivity, the term specificity may be applied at the level of test, screen or programme. The latter is a product of specificity and coverage. **Positive predictive value** is the proportion of individuals with a positive test result who have the target condition.

Yield is used to indicate the number of cases identified by a screen (e.g. in the first 12 months of the first phase of the Newborn Hearing Screening Programme (NHSP) in England, 40 true cases of bilateral permanent hearing loss were identified via the screen). The yield is sometimes expressed as the number of cases identified via the screen per 1000 individuals screened, thus allowing comparison with published prevalence figures, and acting as a surrogate for sensitivity (since sensitivity can only be established in retrospect, once all false-negative and missed cases have been found). The yield of a screen is affected by coverage and sensitivity, and affects the cost per case identified. Finally, the **incremental yield** is the number of true cases referred by a screen when any true cases that would have been or were identified by preceding screening, surveillance programmes or responsive services are excluded.

Incidence is the number of new instances of the condition (impairment) occurring during a certain period (e.g. a year) in a specified population. Thus, in an average-sized health community with 5000 births per year, an incidence of between five and ten cases of congenital permanent moderate or greater bilateral hearing loss might be expected.

Prevalence is the total number of individuals who have a given disease or condition (impairment) at a given point in time per population figure (e.g. per 1000 live births). Davis *et al.*⁴ have suggested a figure of 1.12 per 1000 for congenital permanent bilateral hearing impairment of moderate or greater degree (see under Prevalence and risk factors below for further discussion of prevalence figures).

The extended Wilson and Junger screening criteria identify costs and effectiveness as important issues for screening programmes (points 9 and 14 above). **Cost-effectiveness analysis** is an economic analysis used to compare effectiveness and cost of health interventions in which either (1) effects of the interventions are known to be equal and so the option to be recommended is that which is least (or less) costly (sometimes known as 'cost-minimization analysis') or (2) effects and costs differ across interventions; hence, the option to be recommended is that with the lowest (or lower) ratio of cost per unit of health gain, as implementation of this option will lead to the most (or more) effective use of a fixed budget.

PREVALENCE AND RISK FACTORS

Congenital permanent bilateral hearing loss

The quality of published studies on the prevalence of congenital permanent hearing loss is variable, with the poorer studies marred by lack of clarity on case definition, uncertain methodology and doubtful case ascertainment. Of the better studies, those reported by Davis *et al.*⁴ and Fortnum *et al.*^{5,6} are probably the most extensive and reliable. Fortnum *et al.*⁵ report the results of a retrospective ascertainment of all cases of permanent bilateral hearing loss of moderate or greater degree in children born in the UK's Trent health region between 1985 and 1993. Considerable effort was put into the ascertainment process such that the authors believe that over 90 percent of all known cases were found. Based on the birth cohorts for 1985–1990, the prevalence of moderate-to-profound congenital permanent bilateral hearing loss was 1.12 (95 percent CI 1.01–1.23) per 1000 live births (0.64 per 1000 for moderate hearing loss; 0.23 per 1000 for severe hearing loss; 0.24 per 1000 for profound hearing loss). An even more extensive study is reported by Fortnum *et al.*⁶ In this, the authors carried out a full national retrospective ascertainment of all cases of bilateral permanent hearing loss of moderate or greater degree in the UK, born between 1980 and 1997. Data were collected in years 1998–1999 within a strict ethical framework from both health (audiology) and education (support services for hearing impaired children). Once duplicate data had been excluded, there were 17,160 cases, giving an overall prevalence of 1.33 per 1000 births (95 percent CI 1.22–1.45). However, prevalence varied as a function of age, being 0.91 per 1000 (95 percent CI 0.85–0.98) for the three-year-old cohort and rising to 1.65 per 1000 (95 percent CI 1.62–1.68) for the nine-year-old cohort, where it levelled off. The authors argue that the rise in prevalence with age is not because of any change in prevalence with year of birth, nor can it be ascribed only to later acquired

losses, and they conclude that there are more late-onset and progressive permanent childhood hearing losses than previously suspected. Furthermore, statistical adjustment of the data indicated the possibility of under-ascertainment, such that the final prevalence figure at age nine years might be as high as 2.0 per thousand. While these data support the use of newborn hearing screening for the identification of the 1.12 (or thereabouts) congenital cases per 1000 births, other processes will be needed for the post-natal onset cases. [**]

Risk factors

Risk factors for permanent congenital hearing loss are well established. The risk factors for permanent hearing loss in neonates as suggested by the US Joint Committee on Infant Hearing position statement 2000 are as follows.⁷

- An illness or condition requiring admission of 48 hours or greater to a NICU.
- Stigmata or other findings associated with a syndrome known to include a sensorineural and/or conductive hearing loss.
- Family history of permanent childhood sensorineural hearing loss.
- Craniofacial anomalies, including those with morphological abnormalities of the pinna and ear canal.
- *In utero* infection such as cytomegalovirus, herpes, toxoplasmosis or rubella.

The three major summary risk factors are:

1. history of treatment in an neonatal intensive care unit (NICU) or special care baby unit (SCBU) for more than 48 hours;
2. family history of early childhood deafness;
3. craniofacial anomaly (e.g. cleft palate) associated with hearing impairment.^{4,8}

About 60 percent of congenital bilateral permanent hearing loss of moderate degree or greater is associated with one or more of these three risk factors, in the proportions 29.3 percent NICU, 26.7 percent family history and 3.9 percent craniofacial anomaly. [**] The high proportion of cases with risk factors led, in the early 1990s, to the widespread introduction of 'at risk' newborn screening in which attempts were made to screen all those babies (perhaps some 10 percent of the birth cohort) with risk factors, in order to identify early this 60 percent of the target true cases of congenital permanent loss. However, in practice, due to the difficulty experienced by maternity services in reliably identifying a family history of permanent childhood hearing loss, the proportion of the target population identified by at risk screening was rarely above 40 percent.⁴ [**]

Acquired and late-onset permanent bilateral hearing loss

Acquired hearing loss is a hearing loss acquired post-natally which, on the basis of case history, was not considered to be present and detectable using appropriate tests at or very soon after birth. Post-meningitic hearing loss and hearing loss due to trauma are the most common causes of acquired hearing loss in children. The study by Fortnum *et al.*⁶ has indicated that progressive or late-onset hearing losses may be more prevalent than suspected, having an effect through the preschool and early school years (see Prevalence and risk factors). Any newborn hearing screening programme will of course not identify these cases and this therefore points to the importance of addressing other means of finding them.

Unilateral permanent hearing loss

There are few reliable studies on the prevalence of unilateral permanent hearing loss in preschool children. However, there is some reason to suspect that prevalence may be relatively high. In a retrospective study of children up to the age of ten years, Vartiainen and Karjalainen⁹ found a prevalence of 1.7 per 1000 live births for permanent unilateral sensorineural or mixed hearing loss (> 25 dB HL at 0.5–4 kHz, including mixed hearing impairments with bone conduction thresholds of ≥ 25 dB HL). [**] The yield for permanent unilateral moderate or greater hearing loss in the Newborn Hearing Screening Programme in England is 0.64 (95 percent CI 0.37–0.91) per 1000 screened. This is new information and has raised a number of issues about the appropriate early management of unilateral permanent hearing loss that have not been faced before.¹⁰ [**]

Auditory neuropathy/dys-synchrony

Auditory neuropathy/auditory dys-synchrony (AN/AD) is caused by damage to inner hair cells, the synaptic juncture between the inner hair cells, auditory neurons in the spiral ganglion, the VIIIth nerve fibres, or any combination. This is observed on clinical audiological tests as normal otoacoustic emissions (OAEs) in the presence of an absent or severely abnormal auditory brainstem response (ABR).

The prevalence of AN/AD is not known. It has been reported that up to 10 percent of all children with confirmed permanent hearing loss have auditory neuropathy.^{11,12}

Infants and children diagnosed with AN/AD typically have a remarkable medical history. It is a condition found predominantly in the NICU population: three in 1000 high-risk babies present with AN/AD¹³ and it is considered relatively rare in the well-baby population.¹² [**]

Temporary childhood hearing loss

Temporary childhood hearing loss due to otitis media with effusion (OME) is extremely common, with a point prevalence of some 20 percent and a period prevalence in the under five-year-olds of some 80 percent.^{3, 14} [**] The major risk factors are season, passive smoking, bottle-feeding, upper respiratory tract infections, admission to NICU as a newborn, day care and siblings having had OME.³ [**] The large scale TARGET (Trials of Alternative Regimes in Glue Ear Treatment) studies currently being carried out in the UK are likely to provide much-needed evidence in a number of domains; careful recruitment of over 300 cases aged 3.5 to 7 years has provided more robust data than have been available previously. Refinement of risk factor analyses has indicated season, passive smoking, siblings having had OME and snoring and mouth-breathing as the best indicators for persistence.¹⁵ The TARGET studies indicate material effects of persistent OME on hearing difficulties, speech/language delay, disturbed sleep patterns, behaviour and (consequent on these) parental and child quality of life. [****]

THE RATIONALE FOR SCREENING

In this section, we will consider screening only with respect to permanent childhood hearing loss.

The critical review (1997) of newborn hearing screening carried out as part of the UK's Health Technology Assessment programme⁴ identified eight broad reasons for the introduction of newborn hearing screening for all babies.

1. Outcomes for at least some children with congenital permanent hearing loss are the cause of considerable concern.
2. Median identification age in the UK for moderate or greater bilateral congenital permanent hearing loss based on current screening tests was around 22 months.
3. There is evidence that intervention in the first six months of life for children with moderate or greater permanent bilateral hearing loss can improve at least some outcomes.
4. More precise and detailed neural connections depend upon appropriate early stimulation; myelination of auditory pathways by six months of age is delayed by almost any chronic insult.
5. Early identification allows early and more appropriate management decisions, made not from a starting point of developmental deficit.
6. Costs of newborn screening look to be broadly acceptable.
7. Evidence from parents of deaf children strongly suggest that they would have welcomed very early identification.

8. Evidence from parents suggest that they would welcome a newborn hearing screen.

Early deprivation and early plasticity

Studies with animals have shown that deafferentation of the auditory system during early sensitive periods of development results in marked anatomic and physiological changes that occur extensively throughout the central auditory system.^{16, 17, 18} [****] The first study to demonstrate that, within the sensitive period, changes wrought by loss of afferent input could be reversed was carried out by Pasic and Rubel.¹⁹ They showed that in neonatal gerbils, changes in cochlear nucleus cell size produced by auditory nerve blocking by tetrodotoxin were completely reversible after seven days. [****] There appears to be considerable plasticity in the whole pathway during early development, but in the adult subject plasticity at lower neural levels (e.g. brainstem, midbrain) is considerably reduced and possibly lost.²⁰ This indicates that the early post-natal period is crucial for the establishment of auditory pathways that can accurately represent complex sounds at the cortical level. There appears to be a critical period of plasticity at lower pathways of the auditory system. [****]

Outcomes

There is good evidence that outcomes in a number of domains are affected by permanent hearing loss. In most cases this is a severity-dependent effect, with greater effects for more severe hearing losses; there are, however, very great individual differences, with some children performing at levels appropriate to their age and others performing very poorly. These differences are not always a function of degree of hearing loss, but will be a result of a range of intrinsic and extrinsic factors. One such factor is the age at which the hearing loss was identified, as well as habilitative support provided. The evidence of compromised outcomes associated with congenital permanent hearing loss comes from studies looking at communication skills,²¹ literacy,²² behaviour,²³ educational achievement,²⁴ mental health,²⁵ family dynamics²⁶ and quality of life.²³ [**]

Late identification

Since the late 1950s, the UK has had a universal eight-month screen for childhood hearing loss based on the infant distraction test (IDT) (see Chapter 68, Hearing tests in children) and usually carried out by health visitors in community clinic settings. With the introduction of newborn hearing screening this is to be phased out; there is good evidence that it has poor sensitivity,

poor specificity and is not cost effective in terms of cost per case found.^{5, 27, 28} The retrospective study of permanent childhood hearing impairment greater than or equal to 40 dB HL in children born between 1985 and 1993 and resident in Trent health region, showed that the median ages at referral, confirmation of the impairment, prescription of hearing aids and fitting of hearing aids were, respectively, 10.4, 18.1, 24.4 and 26.3 months.⁵ [**] While much of the delay was clearly due to delays in the assessment process after referral, nonetheless the median age of screen referral for children with congenital hearing loss was little short of one year.

Benefits of early identification and intervention

Yoshinaga-Itano *et al.*²⁹ compared the receptive and expressive language abilities of 72 children with hearing loss who had been identified by six months of age with 78 children whose hearing losses were identified after six months and showed that early-identified children demonstrated significantly better language scores than the later-identified children. For children with normal cognitive abilities, this language advantage was found across all test ages, communication modes, degrees of hearing loss and socioeconomic backgrounds. It was also independent of gender, ethnicity and the presence or absence of additional disabilities. [***]

This finding is consistent with a number of similar studies of variable quality, all reporting significantly better language scores for children whose hearing losses were identified earlier.^{30, 31, 32, 33, 34, 35, 36, 37} [***/**]

Even though evidence from randomized controlled trials is not available to address the question of whether earlier rather than later intervention is better for children with hearing loss, the consistency of findings from a number of quasi-experimental studies provides consistent and convincing evidence about the benefits of earlier intervention.

Assessment and management

Some aspects of audiological assessment are easier in the first few months of life: for example, unsedated electrophysiological tests such as the auditory brainstem response, and habilitative procedures such as real ear measurements for hearing aid fittings, or ear impressions for earmoulds. Perhaps more importantly, the earlier that parents and services know about the child's hearing loss, its degree and the child's progress, the earlier can decisions be made about management (e.g. appropriate hearing aids, first language, extent and type of family support).

Costs

While further cost-effectiveness studies are required, it is clear that the costs of newborn screening are broadly acceptable.⁴ Stevens *et al.*²⁸ compared the costs of newborn hearing screening of all babies in three areas already implementing such a service, with costs of the IDT screen in seven areas, and found that the mean service costs for the universal newborn hearing screen and the eight-month IDT screen were £13,881 and £24,519, respectively, for a standardized district of 1000 live births; the cost per case found was much lower for newborn screening due to the higher sensitivity of the screen. [**]

Parental wishes

Finally, there is the issue of parental rights to significant information about their child. This has been given expression in a number of surveys, the largest of which is that by Watkin *et al.*³⁸ He investigated the attitudes of parents of deaf children to newborn hearing screening. If such a procedure had been available to them when their child was born, 89 percent said they would have wanted it. It is also known that early identification tends to avoid the parental anxiety and anger that may be associated with delayed detection.^{38, 39} [**]

NEWBORN HEARING SCREENING

Current screening tests available

The tests used for newborn hearing screening are currently one or more of:

- automated otoacoustic emissions (AOAE);
- transient evoked otoacoustic emissions (TEOAE);
- distortion product otoacoustic emissions (DPOAE);
- automated auditory brainstem response (AABR).

TEOAE reflect the activity in the outer hair cells of the cochlea, while AABR waveforms are affected by cochlear and neural lesions. These methods are described in detail in Chapter 68, Hearing tests in children and Chapter 69, Investigation and management of the deaf child.

It is important to note that a newborn hearing screening programme protocol that regards a clear OAE result as a screen pass will miss neonates with auditory neuropathy, since the latter will manifest with OAE present, but ABR absent. Because auditory neuropathy is predominantly found in the NICU/SCBU population (and according to Sininger¹³ as many as three per 1000 neonates enrolled in NICU/SCBU may have auditory neuropathy), AABR is the method of choice in the NICU/SCBU population. [**] In the UK Newborn Hearing Screening Programme (www.hearing.screening.nhs.uk),

both AABR and TEOAE is required for NICU babies, while for well babies the two tests are done in series, with only those without clear bilateral responses on OAE going on to AABR. This ordering is driven by the time required and the costs associated with AABR as opposed to OEA.

Cut-off level and case definition

While many North American programmes^{40, 41} target all babies with permanent hearing loss, including mild and unilateral hearing losses, the Newborn Hearing Screening Programme in England aims to identify all children with a permanent hearing loss of 40 dB HL or greater averaged over the frequencies 0.5, 1.0, 2.0 and 4.0 kHz for the better hearing ear.⁴ As a byproduct, the screen will also identify a number of babies who have unilateral and in some cases mild hearing loss, but the consequences of delay in identification are not well established in these infants, and most are not candidates for hearing aids or other therapies associated with early identification.⁴² [**] However, this is lack of evidence for effects rather than evidence of no effects, and research is underway to identify best practice for the early management of congenital permanent mild and unilateral hearing loss.

Models for universal newborn hearing screening

The most commonly used model to date has been a hospital-based screen employing a team of dedicated screeners performing the screening tests on neonates on the maternity unit before discharge. This is backed up by a recall clinic for the babies missed by the initial screen.^{27, 42} However, in some European countries, a community-based screening model integrated into an existing framework of preventive health care has been used with considerable success.^{43, 44} Owen *et al.*⁴⁵ reported that it was feasible for health visitors to perform neonatal hearing screening in the community and achieve very high coverage and low false-positive rates. The assumption is that community-based screening also results in higher parental satisfaction, but this is yet to be established. [**] Some areas in England are using a community-, rather than hospital-based model and cost-effectiveness comparisons are being undertaken.

'At-risk' screening

Risk factors for permanent congenital hearing loss are well established. Davis and Wood⁸ showed that babies admitted to a neonatal intensive care unit for more than 48 hours were 10.2 (95 percent CI 4.4–23.7) times more likely to have a permanent hearing loss (greater than 50 dB HL in this study) than those who did not undergo

intensive care. Fortnum *et al.*⁵ showed that prevalence was increased 14-fold for children with a family history of early permanent childhood deafness. Babies with cranio-facial anomalies associated with hearing impairment (e.g. cleft palate) are also at high risk for hearing loss. The large-scale Wessex study²⁷ reported that, of 25,000 newborns screened, 8.1 percent fulfilled high-risk criteria for permanent childhood hearing loss.

Thus, targeted newborn hearing screening looks like a desirable option, as only a small proportion of babies would need to be screened. The yield is potentially high: just 86–208 high-risk babies need to be screened to find one baby with hearing loss as opposed to a yield of one per 2041–2794 low-risk babies screened.^{27, 46, 47} Thus, it has been argued that targeted newborn hearing screening is a relatively inexpensive way of improving the age of identification for a significant proportion of children with congenital hearing loss.²⁸

However, there are a number of disadvantages to targeted newborn hearing screening. Stevens *et al.*²⁸ noted that some 'at risk' infants, in particular those with a family history of hearing loss, are not being referred for screening. More importantly, some 40 or 50 percent of babies born with permanent hearing loss demonstrate no risk factors. Numerous studies agree that around half of all affected infants have no risk factors at birth and thus would be missed by a targeted hearing screening.^{5, 12, 41, 48}

Performance of universal newborn hearing screening

Davis *et al.*⁴ reported in their critical review of the evidence that high coverage of over 90 percent was possible with hospital-based newborn screening programmes. The current newborn hearing screening programme in England has completed the screening in 96 percent of all target babies,¹⁰ [**] which is well within the set quality standards.

Davis *et al.*⁴ also concluded that screen sensitivity was estimated to range from 80 to nearly 100 percent and that screen specificity was above 90 percent. Specificity has been shown to gradually but significantly improve as advances in technology, use of two-stage screening (i.e. two tests) and training methodology evolve.^{41, 49} [****/**] Davis *et al.*⁵⁰ concluded that all methods of neonatal hearing screening appear to have high test and screen sensitivity, which can be extended to programme sensitivity in both universal and targeted neonatal hearing screening programmes given sufficient resources. The authors also concluded that TEOAE screens and TEOAE/AABR combined screens in particular have high screen specificity for full-term babies shown in several different implementations. [**] Screen specificity is influenced by whether the protocol requires a clear response in both ears or in either ear. For example in the Wessex study, to facilitate lower failure rates, more rapid screening and

greater coverage, a unilateral clear TEOAE response was accepted as a pass in infants younger than 48 hours.²⁷ [****]

Programme sensitivity has been shown to be around 80 percent.⁴ [***] The yield has been shown to be very high. To find one child with bilateral moderate-to-profound hearing loss 755–1422 newborns have to be screened.^{27, 42, 47} Yield is even higher, of course, if unilateral and mild cases are included.^{41, 51} [**] The median age of identification for those screened neonatally is of the order of two months.^{10, 42, 46, 52} [**]

It is important to note that these data are derived from a rather few, though large, published studies of universal newborn screening.^{27, 42, 51} Only the Wessex study²⁷ is a controlled trial (but not a randomized controlled trial). The extent to which these encouraging results can be translated into a national screen is an issue being addressed by the national evaluation of the first phase of the Newborn Hearing Screening Programme (NHSP) in England.

Cost-effectiveness

Stevens *et al.*²⁸ found that in comparison to the IDT screen, universal newborn hearing screening has acceptable costs. They calculated the mean service price for universal hearing screening in three services and, for the IDT test screen, at 1994 prices, these were £13,881 and £24,519, respectively, for a standardized district of 1000 live births. [**]

The cost of universal newborn hearing screening compares favourably with screening for other congenital conditions, e.g. hypothyroidism, phenylketonuria or haemoglobinopathy.⁵³ It has been argued that universal newborn hearing screening will have paid for itself within ten years in terms of the long-term savings made in special education and social interventions.⁵³ However, longitudinal data do not yet exist. [**]

'Family-friendliness'

Since screening takes place over the very first days or even hours after the baby's birth, one of the main concerns associated with newborn hearing screening is the risk of causing unnecessary anxiety for the family.

Several studies on parental opinions show that in general parents were very positive about newborn hearing screening and that the risk of disturbing the parent-child relationship by early screening seemed small and could be further minimized by improved information and rapid and effective follow-up.^{10, 38, 54, 55, 56, 57} [**] The current implementation of the NHSP in England has developed a number of processes for ensuring high levels of information for mothers/parents, including a national screener-training programme, training and information sessions

for other professionals, plain English information leaflets, written parental consent to the screen and so on. The extent to which these have minimized levels of anxiety in the mothers of babies passing the screen at different stages, and those whose babies are referred by the screen, is being investigated. The effects of early identification on the family are being investigated in true cases by in-depth interviews with parents.

Quality assurance

There is an ethical duty within a screening programme (particularly a national programme) to ensure that good quality services are in place prior to the start of the screening programme and that they continue to meet national guidelines. It is most important to promote an evaluative culture to enable continued service improvement in both technical and family-friendly service delivery.

Quality standards for early identification and management of congenital permanent hearing loss have been developed in the USA⁷ and the UK.^{58, 59} Consensus statements on newborn hearing screening have been developed in the USA⁷ and in Europe.⁶⁰

Some of the quality standards adopted by the current Newborn Hearing Screening Programme in England are shown in Table 67.1.

THE EIGHT-MONTH IDT SCREEN

The eight-month IDT screen has been in place as an almost universal screen across the UK since the late 1950s. It is being phased out as the Newborn Hearing Screening Programme is implemented. While protocols and test

Table 67.1 Quality standards for the NHS Newborn Hearing Screening Programme in England.

Quality standards
Initial programme coverage >90% of all live births by discharge
Screen coverage including call back >95% of all births by six months
Coverage of NICU/SCBU 99% of live discharge
Referral rate for non-NICU/SCBU <3%
Referral rate for NICU/SCBU <5%
All screen referrals followed up with audiological assessment by three months of age ^a
True cases confirmed by six months of age for all cases
Hearing aid fitted for all true cases within four weeks of confirmation ^b
Education services informed of all true cases within three working days

^aUnless deliberately delayed for diagnostic reasons or follow-up refused.
^bUnless deliberately delayed for management reasons.

details vary from area to area, the most typical format involves a two-person distraction test, using frequency-specific stimuli (low, mid and high frequencies) presented at quiet levels (e.g. 35 dBA) to the side and slightly behind (at 45°) the eight-month-old infant who is seated on the parent's knees. A full localization response to all stimuli on both sides represents an acceptable pass. Failures are usually retested once at a later date, except in the case of obvious concern, and two test failures constitutes a screen referral. This may be made to a secondary or tertiary audiology department, to a general practitioner for onward referral, or to an ear, nose and throat (ENT) department.

The screen cannot be used in the first six months of life and therefore it cannot support the start of intervention before six months of age. Evidence on the performance of this screen is reviewed by Davis *et al.*⁴ The median age of identification through the IDT screen varies from 12 to 20 months; coverage falls in the range of 80–95 percent, although there may be some urban areas where coverage is as low as 60 percent. Sensitivity estimates of the IDT screen vary from 18 to 88 percent according to the service area. Screen sensitivity is greatly influenced by the degree of hearing loss, with higher sensitivity for more severe losses; even so, there have been too many cases of profound hearing losses passing the screen. Low coverage and low sensitivity result in unacceptably low incremental yield, in the range of 25–40 percent. The failure rate is high at 5–10 percent, largely because of poor practice and because of a high number of referrals due to transient OME. The referral rate has considerable resource implications for services. [**]

Because of its low yield, the IDT screen has not proved to be cost-effective. Davis *et al.*⁴ estimate the cost per child detected with permanent bilateral hearing loss to be between £81,700 and £102,100 (\$166,366 and \$207,906), as opposed to £9900–£19,700 (\$20,159 and \$40,115) per child detected through a hospital-based newborn hearing screening programme. [****]

There have been consumer concerns about the quality of the IDT screen. Studies have shown that the subjectivity of the test has caused parents not to take the test seriously, which has contributed to low coverage and low interest in attending follow-up appointments.^{61, 62} [**]

Because of widespread dissatisfaction with the IDT screen, there have been some attempts to substitute 'vigilance' programmes based on questionnaires to parents. Sutton and Scanlon.⁶³ showed that a vigilance programme was likely to perform as well as the IDT screen (but no better) for severe and profound hearing losses, but less well than the IDT screen in referring moderate hearing losses. [**]

THE SCHOOL-ENTRY SCREEN

The school-entry hearing screen is currently employed universally across the UK. It consists of a modification of

standard pure-tone audiometry, with test signals presented at specific frequencies and at fixed levels (the 'sweep' test). The cut-off level is set at 20 or 25 dB HL. One or two tests may be performed, usually during the first year of school entry. The screen is usually carried out by a school nurse, but may be done by a school doctor or audiology technician. Testing is generally done within the school and ambient noise may limit specificity. There is currently very little monitoring or evaluation of the school entry screen. Guidelines for training and testing for non-audiology professionals have been issued.⁶⁴

Apart from referring children with progressive and acquired permanent hearing loss that have not been picked up by parental observation and responsive services, the school-entry screen also has the potential to identify children with mild and unilateral hearing loss, as well as high-frequency hearing loss and other hearing losses with unusual configurations. It may also have a role in identifying children with marked hearing loss due to OME, and is thought to be a reasonably cost-effective way of raising awareness of the importance of good hearing at a crucial stage of the child's education and development. However, these assertions remain to be tested by good quality research.

SURVEILLANCE

As we saw earlier, child health surveillance is regarded as one component of child health promotion programmes which encourage partnership between parents, children and health professionals and in which parents are empowered to make use of services and expertise according to their needs. Surveillance for childhood hearing loss is of considerable importance, since (1) newborn hearing screens will not find all those with preschool permanent hearing loss, because of late onset and progressive hearing loss; (2) any screening programme will miss an irreducible minimum of true cases; and (3) surveillance is a more justifiable approach to identification of children with persistent OME than a screening programme.

At present, there are only rather general guidelines for ongoing surveillance for childhood hearing loss.⁶⁵ A UK working group is currently developing more detailed recommendations. These require a hearing assessment by an appropriately trained audiology team at around eight months of age for all babies who did not give clear bilateral responses in the newborn screen, in particular those found to have permanent unilateral or permanent bilateral mild loss. Naturally all babies who missed the newborn screen or audiological follow-up for whatever reason (e.g. declined the newborn hearing screen, moved out of the area, etc.) need a follow-up by an audiologist at eight months of age. They also require that all children who are at risk for late onset or progressive deafness be offered regular hearing assessments by audiologists at

appropriate ages, irrespective of the newborn screen outcome. These include infants with family history of childhood hearing loss;⁶⁶ a history of severe hyperbilirubinaemia;⁶⁷ evidence or suspicion of congenital infection;^{68, 69} presence of neurodegenerative or neurodevelopmental disorders; all infants with confirmed or suspected meningitis;⁷⁰ those at high risk of persistent middle ear problems as well as sensorineural loss (e.g. children with cleft palate or Down syndrome);⁷¹ and other craniofacial anomalies, including chromosomal or syndromic conditions, including branchial arch and cervical spine anomalies.⁷² Surveillance policies should encourage services to be highly responsive to parental or professional concern about a child's hearing or their development of auditory, vocal or communicative behaviour; such infants should be offered a full hearing assessment at any age by an appropriately trained team. The importance of ongoing surveillance by health visitors, family doctors, community health teams, as well as parents (reinforced by appropriate check lists such as those given to parents shortly after the birth of their child), should not be underestimated, since it will help to deal with the increasing prevalence with age found by Fortnum *et al.*⁶ in their extensive prevalence study.

SURVEILLANCE FOR OTITIS MEDIA WITH EFFUSION

Screening for either OME (the pathology) or for the consequent hearing loss (the impairment) fails to meet the criteria for screening programmes outlined under Principles and definitions above. On the other hand, we know that there are material effects upon speech/language, behaviour, physical well-being and quality of life for both parent and child in persistent cases. Some sort of surveillance system needs therefore to be in place for identifying and intervening with those 5 or 10 percent of cases that have OME with a persistence or severity likely to interfere with development. The TARGET group has shown that a screening questionnaire to parents on OME history and hearing loss gives only slightly lower sensitivity but similar specificity to that from school-entry screening. For OME, such questionnaire approaches to surveillance gain over screening, since the fluctuating nature of the condition tends to make a one-off screen misprecise, while parental reports tend usefully to average the observed effects over time.¹⁵ [****]

'Watchful waiting' for three months has been shown to be an effective strategy for confirmed cases picked up by responsive services. Some 50 percent of such cases resolve after three months and do not justify further management unless the condition recurs.^{14, 15} The only exception to the advisability of having a watchful-waiting period arises in children with a pure-tone average in the better ear ≥ 30 dB HL at their initial visit, who have a prior audiogram to

confirm OME, and who are sent to ENT between August and December. In these children the probability of persistence is greater than 80 percent. [****] If good audiometry is not available in primary care (because of lack of equipment or expertise), tympanometry has been confirmed as sensitive and fairly specific in identifying children with material hearing loss associated with OME.¹⁵ [****] On the other hand, it has been shown that little equipment is available or used to support OME assessment in UK primary care. However, it has also been shown that the use by family doctors of a simple checklist and a training video significantly improves the positive predictive value of their referrals.¹⁵ [****]

The aim for services must be to identify those children who have persistent OME to the extent of being at risk for hearing and speech/language deficits, behaviour problems, quality of life, and, in a few cases, educational deficits.

KEY POINTS

- At least one in 1000 children is born with permanent bilateral hearing loss ≥ 40 dB HL.
- If permanent bilateral congenital hearing loss is identified before six months of age and habilitation started soon thereafter the adverse effects are lessened.
- By the age of nine years, the prevalence of permanent bilateral hearing loss ≥ 40 dB HL is at least 1.65 per 1000 children.
- Newborn hearing screening of all babies is the most cost-effective method of delivering early identification of congenital permanent hearing loss of at least moderate or greater degree.
- More evidence is required on the outcomes for children with permanent mild or unilateral hearing loss, and on alternative approaches to management.
- Screening at eight months using the infant distraction test is not cost-effective.
- School-entry screening may be cost-effective, but there is little evidence to judge as yet.
- Since prevalence continues to rise in the first few years of life, other methods based on surveillance and responsive services need to be in place.
- OME is a very common condition which may lead to hearing loss, delays in speech/language, behaviour problems and reduced quality of life in persistent cases.
- Identification of persistent OME cases depends upon good surveillance systems in primary care and responsive services.

Best clinical practice

- ✓ Newborn hearing screening of all babies is the most cost-effective way to identify congenital hearing loss.
- ✓ The eight-month infant distraction test screen is not cost-effective and cannot be justified.
- ✓ A surveillance programme needs to be in place to help identify late onset and acquired hearing losses, backed up by fast responsive services.
- ✓ Every effort should be made to minimize family anxiety by good-quality information and rapid and effective follow-up.
- ✓ Good quality services for true-positive cases based upon informed choices for parents are central to the introduction of a screening programme at any age, but particularly for newborn screening.
- ✓ Management of true-positive cases will involve close cooperation between health, education and social services.
- ✓ Parents and professionals in primary care need to be alert to the presence of persistent OME in some children; identification of these children is improved by the use of checklists and a training video by family doctors, and by a standardized 'screening' questionnaire to parents at varying times.

Deficiencies in current knowledge and areas for future research

- Even though there is evidence to show that parental anxiety associated with newborn hearing screening is fairly minimal, ways of reducing it further need to be investigated. In addition, more understanding of the experiences of the families whose babies are identified with hearing loss at a very early age is needed, in order to ensure that the service received at this early and sensitive stage is 'family-friendly'.
- There are a number of different ways to run a successful newborn hearing screening programme, in terms of equipment, tests and protocols. More work on the modelling of cost-effectiveness under different conditions (e.g. urban versus rural, size of the birthing hospital, the pattern of discharge, etc.) would be helpful.
- Auditory neuropathy is a relatively new condition to audiology services. More research is needed concerning the prevalence, aetiology, outcomes, diagnostic and habilitative options for children with this condition.
- Currently, children with mild and unilateral hearing loss will be identified as a by-product of newborn hearing screening for permanent bilateral hearing losses of ≥ 40 dB HL. More research is needed about

the prevalence, effects, outcomes and habilitative options for these children.

- There is evidence to show that progressive and acquired permanent childhood hearing loss is more prevalent than previously thought. Confirmatory data are needed and evidence on the risk factors for progressive and acquired permanent childhood hearing loss is needed in order to improve surveillance or targeted assessment programmes.
- The school entry screen requires a more extensive evidence base.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words audiometry/child and hearing test/child.

INTRODUCTION

It is essential that suspected hearing loss in young children is promptly investigated. Accurate assessment of hearing is fundamental to diagnosis, investigation and rehabilitation. The techniques applicable to adults and older children are often inappropriate for the young child and for the older child or adult with special needs, particularly learning disability. Skilled testing by trained personnel in a suitable test environment is essential. Electrophysiological events in response to a sound stimulus may be recorded (electrophysiological testing). This is considered in detail in Chapter 67, Hearing loss in pre-school children: screening and surveillance and Chapter 233, Evoked physiological measurement of auditory sensitivity. The focus of this chapter is on those tests that require skilled observation and recording of the child's response to one or more sound stimuli. Testing is increasingly required to monitor speech perception in children with hearing aids and cochlear implants. These 'functional hearing tests' are also considered.

ELECTROPHYSIOLOGICAL TESTING

Key developmental age: 0–6 months, up to adult if appropriate

Electrophysiological techniques including otoacoustic emission (OAE), auditory brainstem response (ABR) and cortical evoked response audiometry (CERA) are discussed in Chapter 67, Hearing loss in pre-school children: screening and surveillance and Chapter 233, Evoked physiological measurement of auditory sensitivity. These methods are mainly employed in newborn screening (see Chapter 67, Hearing loss in pre-school children: screening and surveillance) and diagnostic testing of infants in the first six months.^{1, 2} They can also prove of value in children of any age, when behavioural testing has failed to produce reliable results, in particular, those with severe learning or communication difficulties.³ They may require general anaesthesia. Electrophysiological techniques are also used to confirm hearing thresholds, for example in children with profound hearing loss, prior to fitting of high power hearing aids or cochlear

implantation or where nonorganic factors are suspected. Whilst electrophysiological testing has the advantage of being objective in terms of the child's response, behavioural or speech discrimination testing remain the only functional measures for assessing the complete auditory system.

BEHAVIOURAL OBSERVATION AUDIOMETRY

Key developmental age: 0–6 months

In behavioural observation audiometry (BOA), changes in activity are observed in response to a sound stimulus. Response behaviours in infants up to four months might include eye widening, eye blink (auropalpebral reflex), arousal from sleep, startle or shudder of the body or definite movement of the arms, legs or body. From four to seven months, lateral inclination of the head towards the sound or a listening attitude or stilling may be observed. The test is usually performed with the child cradled in the parent's lap. The child's attention may be lightly engaged in front by a distractor. The sound stimulus is presented for <2 seconds, in a horizontal plane, 15 cm from the child's ear, out of peripheral vision. The distractor observes evidence of a response. A range of sound stimuli may be sometimes employed, including narrow band and warble tones or less frequency-specific examples, such as a small bell, squawky squeeze toy or banging wooden bricks.⁴ [***]

Reliability as a diagnostic test is obviously a concern. A wide variability in judgement of response between testers due to misinterpretation of random movements and a tendency to underestimate hearing thresholds has been demonstrated.⁵ Attempts have been made to reduce observer bias by use of video recording of the procedure and scoring the playback without knowledge of the sound or no sound trials.⁶ [***]

The use of BOA in infants under six months has been largely superseded by the availability of electrophysiological techniques. It does, however, have a continuing role in the assessment of children with severe learning difficulties, who have not reached an appropriate developmental stage for distraction or visual reinforcement audiometry. It may also be of value in cases of auditory neuropathy when ABR is a poor indicator of functional hearing levels.⁷

THE DISTRACTION TEST

Key developmental age: 6–18 months

The test is based on the principle that the normal response observed when sound is presented to a baby is a head turn to locate the source of sound. The test is

suitable for babies from 6 to 18 months, corresponding to the stage when the child can sit erect unsupported and perform head turns in a horizontal plane. An appropriate allowance should be made for prematurity. Habituation is increasingly likely to occur after 12 months, although the technique may prove to be useful in older children with learning or communication difficulties where other methods have been unsuccessful.

The credibility of the infant distraction test as a tool for screening for hearing impairment has become questionable. In many areas, it has been discontinued in favour of electrophysiological testing in the newborn period¹ (see Chapter 67, Hearing loss in pre-school children: screening and surveillance). Nevertheless, it remains a valuable diagnostic technique when used by trained, experienced testers in appropriate settings. The infant distraction test was first described by Ewing and Ewing in 1944,⁸ but was subsequently modified by McCormick⁹ who placed particular emphasis on the use of frequency-specific, calibrated sound stimuli. The test is described with reference to the guidelines outlined by McCormick.¹⁰ [**/*/*]

Test method

The test should be performed in a tidy, uncluttered, suitably sized room (recommended minimum >16 m²) with ambient noise levels <30 dB(A). Two testers are required, one to present the sound stimuli out of vision and the other to control the baby's attention in the forward direction (the distractor). The latter should be responsible for directing the test. The arrangement is shown in Figure 68.1. The child sits on the parent's knee, facing forward and erect, lightly supported around the waist. The distractor directs the attention of the child to a simple activity usually performed on a low table. Suitable examples include spinning a brightly coloured object, using finger puppets or gently pushing a miniature car. In the classic distraction test described by McCormick, the item is covered by the hands which maintain a fine attention control by moving the fingers slightly. The sound stimulus is presented by the second tester, half a second after the item is covered. The distractor observes the child's response.

The second tester should be positioned strictly out of the child's visual field, which can be assumed to extend at least 90° to either side of the child's midline. The sound stimulus should be presented in the horizontal plane to the ears at an angle, set back 45° between 1 m and 15 cm from the child's ear. The shorter distance increases the head shadow effect, thereby increasing the sound stimulus on one side relative to the other. Evidence of asymmetric hearing levels may be indicated by a difference in response thresholds or difficulty in localizing the sound source. Particular care must be taken when presenting the sound close to the ear to avoid visual or tactile clues. The sound

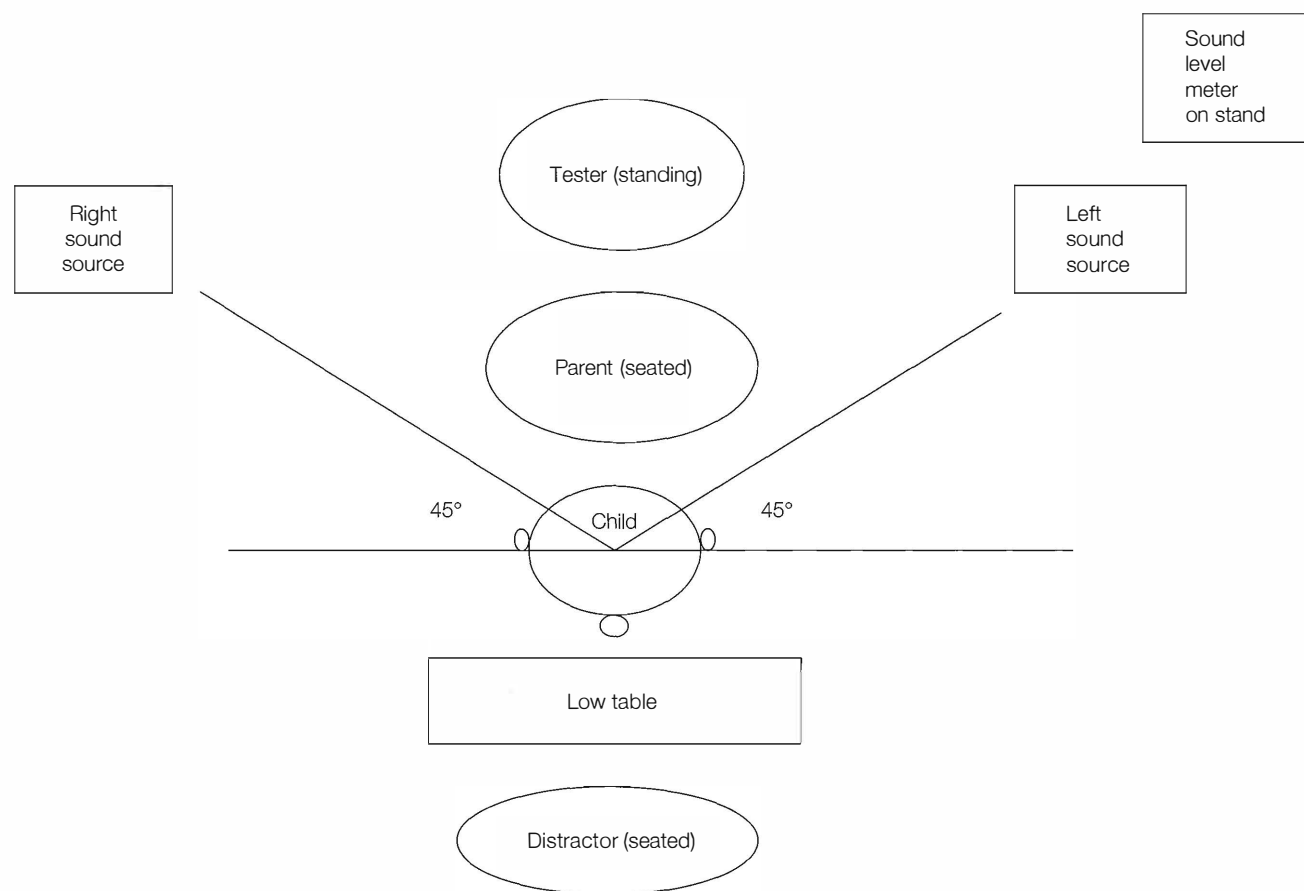

Figure 68.1 Test arrangement for the distraction test.

stimulus should continue up to 10 seconds if there is not an immediate response. During this interval, the distractor should maintain the fine attention control at the front until a response is observed.

The normal response expected is a full head turn in the direction of the sound. This may be rewarded by a smile or vocal praise or gentle tickle from the second tester. Some warble tone generators incorporate a flashing light, which can be activated in response to the turn, providing an incentive to the child and thereby acting as a 'response reinforcer'. The child's attention should then be brought back to the front by the distractor. [**]

The stimulus

A wide range of sound stimuli can be used to elicit a response, including voice, musical toys, 'everyday sounds', narrow band noise and warble tones (see **Figure 68.2**). Pure tones should be avoided due to the potential creation of standing waves, resulting in unpredictable sound levels. Responses to any sound stimulus may be valid, provided the intensity and the frequency spectrum, as delivered at the level of the ear, can be established. A sound level meter should be employed to check the intensity of the stimulus by accurately reproducing the

sound and the distance from the ear. Although it has been demonstrated that babies are more likely to respond to wide band sounds, this will inevitably provide less information regarding frequency-specific hearing as required for diagnosis and possible amplification prescription. Sound generators delivering calibrated narrow band and frequency-modulated warble tones have been demonstrated to be effective at eliciting a response and are therefore generally preferred.¹¹

Initially, a sound stimulus is presented which is anticipated to be likely to be suprathreshold, for example at 70 dB(A) in a child with probable normal hearing. A sound is then presented at the anticipated minimal response threshold, for example, 30 dB(A). The intensity for sound field testing is generally measured on the dB(A) scale, but this can be converted to dB SPL (sound pressure level) if required, particularly for hearing aid prescription fitting.¹²

There is no prescribed order for frequency and intensity of sound presentations. The number of reliable responses elicited by distraction testing may be limited, particularly in children over 12 months who may habituate to the test. It is therefore important to prioritize and focus on those thresholds which would be most valuable for each clinical situation, but would normally aim to include high-, medium- and low-frequency information. This, however,

Figure 68.2 The distraction test: examples of frequency spectra for commonly used sound sources. With thanks to JC Stevens, Department of Medical Physics, Royal Hallamshire Hospital, Sheffield, UK.

may need to be balanced against the benefit of varying the order and side of presentation simply to sustain the child’s interest. [Grade D]

No sound control trials

No sound trials are essential for the validation of response thresholds in a distraction test. Some children exhibit checking or searching behaviour or simply turn towards their parents for reassurance during the test. This can clearly be misleading if it coincides with a sound presentation. It is therefore appropriate to introduce control trials in which the test is performed in the usual manner by both testers, but no sound is generated. If the child appears to make a response, then it must be assessed how this compares to the responses observed to sound trials. Usually a difference is noted which can be used to confirm a true response. However, if the checking responses are indistinguishable from the sound responses, the results must be interpreted with appropriate caution.

Tactics such as increasing the interest of the distracting activity and/or maintaining that activity whilst the sound/no sound is presented may avoid ‘clueing in’ the child. This may be particularly helpful in children over one year. Evidence of visual, tactile or even olfactory clues must also be considered and addressed. [*]

Recording the results

The outcome of each valid presentation and no sound trial should be recorded in chart form, specifying the sound source, frequency range if known and intensity. A tick or a cross may be used to indicate whether a response was observed. The response threshold is regarded as the quietest level at which two out of three clear responses were recorded for each particular sound stimulus. Other observations such as the ability to localize the sound source correctly or any concerns about the test reliability should also be recorded. Table 68.1 lists the most commonly encountered pitfalls in distraction testing and avoidance measures. [**]

Table 68.1 Pitfalls encountered in distraction testing.

Pitfalls	Avoidance measures
Visual, tactile, olfactory clues from parent, distractor or second tester	Critical observation of all parties
'Checking' responses by child	No sound trials
Loss of interest in test, suprathreshold responses	Critical assessment of responses
	No sound trials, if necessary take a break, or sustain distraction activity
	Vary the sound stimulus
	Exchange roles of distractor or second tester
Inaccurate estimation of frequency and intensity of stimulus	Use broader band or more interesting sounds
	Use calibrated sound sources
Extraneous noise, leading to false responses or only suprathreshold response	Measure accurately with sound level meter, trying to reproduce conditions
	Use quiet facilities, ideally a sound-treated room with ambient noise <30 dB(A)
	Observe other auditory clues, e.g. clicking switch on warbler
	No sound trials

VISUAL REINFORCEMENT AUDIOMETRY

Key developmental age: 6–36 months

Visual reinforcement audiometry (VRA) incorporates the principle that young children can be trained by operant conditioning to produce a localizing turn to a visual stimulus in response to a sound stimulus. A technique of conditioned orientation reflex (COR) audiometry was initially described by Suzuki and Ogiba¹³ and was further developed by Liden and Kankkunen¹⁴ who introduced the term ‘visual reinforcement audiometry’. Further developments and modifications to the technique have been described.^{15, 16} VRA is now established as a standard technique within the test battery for hearing assessment in preschool children.^{17, 18, 19} A comparison of VRA with the infant distraction test in children aged 12–25 months has demonstrated that VRA generates more auditory-evoked head turns than an unrewarded sound stimulus and delays habituation so that the test was more likely to be completed.²⁰ The method is described with reference to Widen *et al.*²¹ and Shaw.²² [***/**/*]

The test arrangement see diagram

The test room should be sound-treated to ensure low levels of ambient noise and should ideally be partitioned

to provide an observation area with a one-way window, with access to a communication system between the rooms, such as a radio link. If however, this facility is not available, then it is still possible to perform the test within one room, provided the tester operating the audiometer minimizes the distraction to the child and does not provide any additional clues. A suitable arrangement is shown in **Figure 68.3**. The child is seated on the parent’s lap or on a low chair in front of a low table, with the parent seated slightly behind. A second tester may sit on the other side of the table or adjacent to the child to provide low level play activity. For sound field testing, the speakers may be placed at 45, 60 or 90° from the child and at the same height as the child’s head at a distance of at least 1 m from the ear. Frequency-specific calibration of the sound signal from a test point equivalent to the child’s head position is essential. Alternatively, a calibrated signal may be presented via insert earphones using foam tips or the child’s own ear moulds, if available. This has the advantage of potentially providing more precise ear-specific response thresholds and even offers an opportunity to introduce masking by appropriate presentation of narrow band noise in the contralateral ear. This is particularly valuable in amplification selection and setting.²³ A standard bone conductor may also be used in conjunction with VRA to differentiate between a conductive and sensorineural hearing loss. [**]

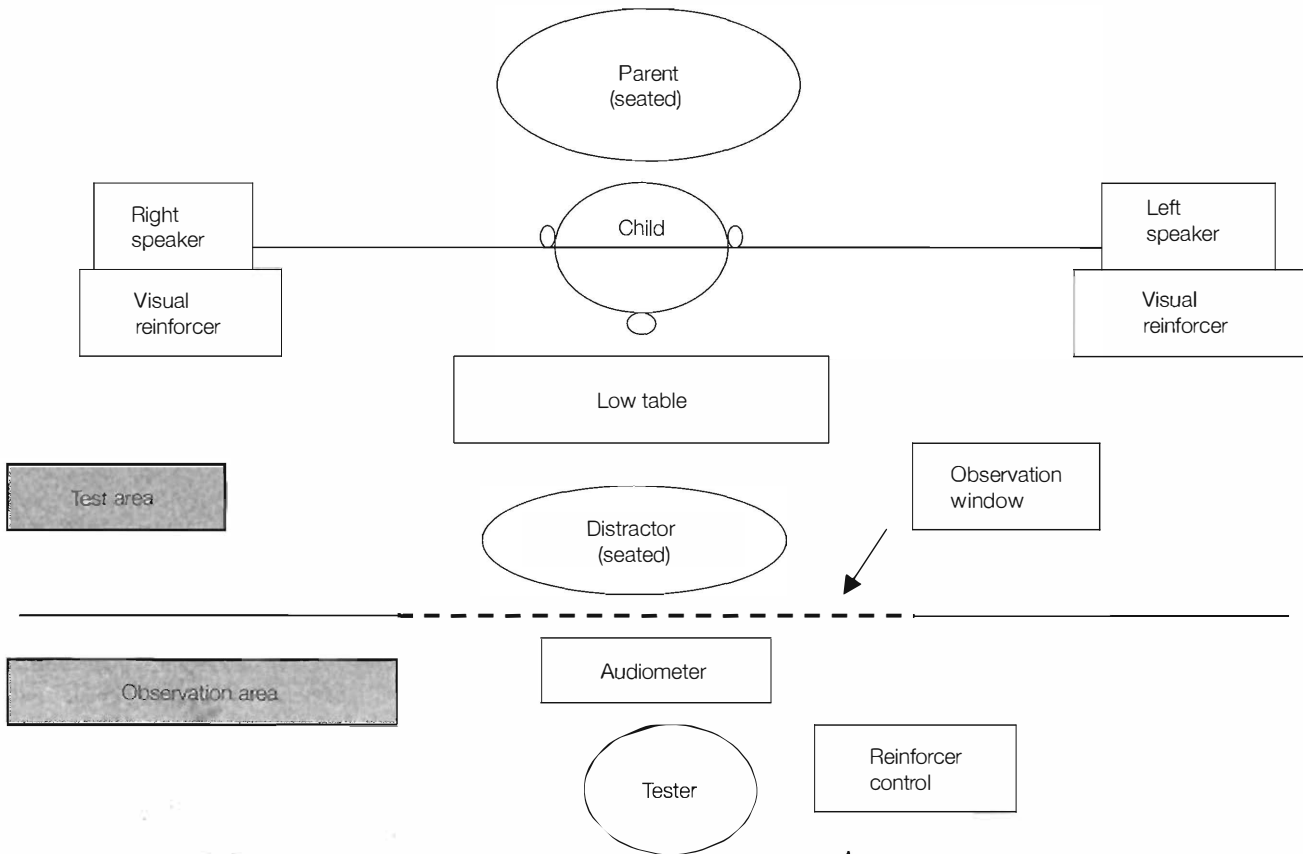

Figure 68.3 The test arrangement for visual reinforcement audiometry.

Thompson and Folsom²⁴ demonstrated that in VRA, unlike distraction testing, the complexity of the signal, including the bandwidth, had no effect on response rate once the child had been correctly conditioned. Frequency-modulated warble tones are generally employed for sound field testing, but pure tones may be used in conjunction with insert earphones or a bone conductor. The frequency sequence should be prioritized according to the clinical situation, but would most often include 0.5, 1.0, 2.0 and 4.0 kHz and in some cases 0.25 and 3 kHz. The duration of the signal is usually two to three seconds.

Visual reinforcers are generally placed adjacent to or above each speaker. The reinforcer acts as a reward and therefore increasing the attractiveness or appeal to the child and introducing variety is likely to sustain interest and reduce habituation. Commercially available reinforcers, include toys with eyes that light up and puppets in darkened glass cabinets which illuminate and dance. Monitors showing appropriate video displays can also be effective. The reinforcer is generally remotely activated by the tester as required. [**]

Test method

Using the arrangement as described above, the first task must be to establish the conditioned response. Having drawn the child's attention to the front by gentle play activity on the table, a suprathreshold auditory signal should be presented concurrently with the visual reward, for example, for a child with probable near-normal hearing, one might start with a 1 kHz warble tone at 70 dBHL. The child may turn to locate the sound (orientation response) and thereby view the activated reinforcer, but if necessary, the child's attention should be directed towards it. This sequence is repeated several times. The sound stimulus should then be presented alone and the reinforcer only activated after the child has produced an appropriate turning response. Praising the child and making it a game will further help to reinforce the response. If this can be reliably repeated two or three times, then operant conditioning has been established. Children under one year or those with learning difficulties may take longer to successfully condition. If it appears that the initial auditory stimulus may be inadequate, this can be cautiously increased or a different frequency or vibrotactile stimulus used.

Once the child has demonstrated successful conditioning, the aim is to establish minimal response levels (MRL) for each frequency, as prioritized by the clinical situation. One reliably obtained MRL is more valuable than a number of 'maybes'. A flexible descending/ascending technique, similar to that used in play audiometry may be applied. Responses should be charted as described for the distraction test, using the two out of three valid

response rule to determine the MRL. No sound control trials should be included to verify a true response and similar measures taken in the event of frequent 'checking behaviour'. MRL less than 20 dBHL can routinely be recorded for frequencies between 0.5 and 4 kHz in normal hearing infants using insert earphone VRA.²⁵ Primus²⁶ found test-retest reliability to be good with 50 percent repeatability within 10 dB. Widen²¹ demonstrated that MRL for at least four frequencies were successfully recorded in more than 90 percent of over 3000 infants aged 8–12 months, tested using VRA. [***]

PERFORMANCE TESTING

Key developmental age: 2–5 years

The performance test was first described by Ewing and Ewing⁸ as a transitional technique suitable for children from 2.5 years and in some cases younger, until co-operation with pure tone audiometry can be achieved. It can be used to assess unaided or aided sound field thresholds. It follows the simple principle that the child is conditioned to wait for a sound and then to respond with a play activity. The test method is described with reference to McCormick.¹⁰ [**]

Test method

The child should be seated on a low chair adjacent to the parent in an uncluttered room with low levels of ambient noise. A toy is placed on a low table in front of the child (Figure 68.4). Toys which involve a simple repetitive activity are most suitable, such as the classic 'men in a boat', balls on sticks, knocking down skittles or pegs in a board. The conditioning sequence starts with the tester engaging the child's attention by holding the response item, e.g. the wooden man, poised waiting in front of the child. After a few seconds, a suprathreshold sound stimulus is presented and the tester responds by an appropriate activity, e.g. placing the man in the boat. This sequence is repeated several times often supported by gestures such as a stop sign using the palm of the hand and a cupped hand to the ear to indicate listening. This has the advantage of avoiding dependence on spoken language. The child is then offered the response item and guided to wait and perform the task as shown. Vocal praise should be used to reinforce a correct response. The number of repetitions required to successfully condition the child will depend on their age, developmental status, willingness to co-operate and in particular their ability to inhibit the response until the signal is detected. It may be necessary to increase the intensity of the signal or initiate conditioning using a vibrotactile stimulus.

© Hodder Arnold / Scott-Brown 7E

Figure 68.4 The performance test.

Once the child has been successfully conditioned to perform the test without guidance, then a flexible descending/ascending technique as described for pure tone audiometry (see Chapter 232, Psychoacoustic audiometry) can be applied to determine the minimal response threshold. The interval between presentations must be randomly varied to avoid a predictable rhythm. No sound trials should be included. It may be necessary to reinstruct the child by guiding a few responses when the stimulus is changed or if the child appears to have lost concentration. It may also be necessary to introduce several changes of activity to sustain interest. This provides the tester with an opportunity to be adaptable and inventive and is part of the joy of audiology! Examples might include knocking the man off the table, flicking a small ball into a 'goal', or even poking the tongue out at the tester. The aim is to be fun enough to motivate the child, whilst being accurate enough to provide valid responses.

The stimulus

In the original description of the performance test, the signal used was a voiced 'go' (low frequency), or a sibilant 's' (high frequency).⁸ When using voiced signals it is essential that the face is totally outside the child's visual field and the mouth is shielded to prevent any awareness of air movement. The tester should therefore adopt a position similar to that described for distraction testing. Frequency-modulated warble tones with stimulus duration of one to three seconds are now the preferred option, providing low-mid and high frequency-specific signals by means of portable sound field noise generators. These should ideally also be used out of vision with care to avoid clues such as a clicking switch. Alternatively, loudspeakers can be utilized in a similar arrangement to that described for VRA. Whatever the signal, it is essential that the test conditions are reproduced accurately to

calibrate the intensity delivered to the child's ear. The sequence of presentation would normally aim to include stimuli at 0.5, 1, 2 and 4 kHz and possibly 0.25, 3, 6 and 8 kHz.

PURE TONE AUDIOMETRY

Key developmental age: 3 years onwards

The techniques employed in performance testing naturally lead into pure tone audiometry, as the child matures. This progression should be adapted to the individual child's ability and co-operation and to the clinical priority. It may be possible, for example, to introduce a bone conductor before a child will tolerate headphones or alternatively, a child who is accustomed to wearing hearing aids may comply with insert earphone audiometry via their ear moulds, as a progression from VRA. Insert earphones have the advantage of increasing transcranial attenuation reducing 'cross over' and of reducing the effect of ear canal collapse which may occur with supra-aural headphones. Again, it is important to sustain interest and concentration by the appropriate use of toys and praise.

The recommended procedures for pure tone audiometry based on the Hugson and Westlake descending/ascending technique using 10/5 dB steps should be flexibility adapted (see Chapter 232, Psychoacoustic audiometry). There is no standard for the interpretation of results in children and the accepted limits of normality range from 15 to 30 dBHL in clinical and screening practice. Nielsen and Olsen²⁷ reported that it was possible to obtain at least six ear-specific air conduction thresholds from virtually 75 percent of three year olds. The introduction of standard masking techniques, where appropriate, will depend on the child's cognitive developmental level and co-operation, but may not be reliable until the age of seven years. [**]

AUDITORY SPEECH DISCRIMINATION TESTS

The ability to discriminate speech signals may be a valuable measure of functional hearing in children with normal to moderate degrees of impairment and is also increasingly used in the evaluation of more severely affected children supplied with hearing aids or cochlear implants. The test batteries developed for use in these latter situations are discussed elsewhere (see Chapter 232, Psychoacoustic audiometry). The tests described below represent a selection from a wide range available and are for use in more general clinical situations.

The co-operative test

LINGUISTIC DEVELOPMENTAL LEVEL: 18–30 MONTHS

This is another test originally described by Ewing and Ewing⁸ and requires the child to discriminate three different simple instructions, e.g. having been handed a small toy, asked to 'give it to Mummy' or 'give it to teddy' or 'give it to baby'. Starting at a suprathreshold level, the voice is then dropped and visual clues removed by covering the mouth. A child with normal hearing may discriminate the instruction at 35–40 dB(A). [Grade D]

Toy discrimination tests

LINGUISTIC DEVELOPMENT LEVEL: 30 MONTHS ONWARDS

Several generations of toy or picture tests have been progressively developed and refined including the Stycar test,²⁸ the Manchester picture test²⁹ and the McCormick toy test³⁰ which is widely used in the UK. This employs seven pairs of similar sounding nouns such as /cup/ and /duck/ or /tree/ and /key/, each represented by a small easily recognizable toy, placed on a table in front of the child in a quiet room. Using live voice, the child is asked to 'show me the ... spoon', etc. Having established an understanding, the voice level is dropped and visual clues removed by covering the mouth. The speech discrimination score is taken as the quietest level at which the child correctly identifies 80 percent of the toys including the paired consonants. For a child with normal hearing this would be expected to occur at ≤ 40 dB(A). A digitized recorded version of the test 'the Parrot' utilizes a small loudspeaker to deliver the instruction at variable intensities.³¹ [***]

Consonant discrimination tests

LINGUISTIC AGE: OVER 6 YEARS

A number of test packages have been designed to specifically examine auditory discrimination of

consonants and intonation patterns, such as the imitative test of speech pattern contrast perception (IMSPAC)³² and the four alternative auditory feature (FAAF) test.³³ There is increasing use of interactive computer-based programmes, but these have so far mainly been employed in the evaluation of hearing aid benefit and for research purposes. [***]

Older children from around the age of eight years may be compliant with formal speech audiometry, in quiet or noise, as described in Chapter 232, Psychoacoustic audiometry.

HEARING ASSESSMENT IN CHILDREN WITH SPECIAL NEEDS

Approximately 30 percent of hearing-impaired children have an additional disability.³⁴ Hearing assessment in children with special needs may be challenging and techniques must be appropriately adapted. For children with learning difficulties, the test most suited to their developmental level, rather than chronological age should be selected (www.nhsp.info).³⁵ Clear simple demonstrations of conditioning tasks may require multiple repetitions to achieve understanding. In children with motor delay or physical disabilities, such as cerebral palsy, the required response must be tailored to the child's capability. In distraction testing, for example, a partial head turn, eye glide or stilling may be judged as an acceptable response provided it is reproducible and validated by no sound trials. In VRA, it may be necessary to bring the visual reward closer and to accept an eye glance response. For performance testing and pure tone audiometry, the conditioning task may need to be modified, such as knocking over a skittle on a stand with a head movement, hitting a drum or even a reproducible postural change. Visually impaired children will turn to locate a sound from around eight months, but are more likely to respond to familiar sounds or if the response is reinforced by a tactile reward, such as touching the sound generator. The use of brightly illuminated reinforcers in a darkened room may facilitate VRA in the partially sighted. Assessment of hearing in a child with autistic spectrum disorder may present the greatest challenge, due to the characteristic self-directed behaviour and lack of shared attention, making interaction with the tester difficult. The repetitive nature of performance testing may particularly appeal to some, but in others distraction testing may be effective, particularly using electronically generated sounds. The child may not comply with sitting on a chair at the table and it may be necessary to take the test to the child, for example sitting on the floor in the corner of the room. Many autistic children are hypersensitive to noise and care must be taken to avoid distress. [**/*]

KEY POINTS

- Accurate testing of hearing is essential in the diagnosis and management of childhood hearing loss.
- Testing and accurate assessment of the test results requires considerable skill and expertise.
- A 'menu' of tests is available depending on the child's age, the availability of expertise and the purpose of the test.
- More than one test method may be needed.
- Testing children with special needs is particularly challenging.

Best clinical practice

- ✓ Be age-appropriate: use the test technique that is most suited to the child's age, developmental status and willingness or ability to co-operate.
- ✓ Be specific: know what you are testing. Calibrate the frequency and intensity of the sound stimulus.
- ✓ Be valid: reproducibility and use of 'no sound trials' are essential. Avoid other clues. Children can make good cheats.
- ✓ Be adaptable: nonstandard techniques may be best in nonstandard children.
- ✓ Be fun: children easily get bored and frightened. Their co-operation is required. Use toys and smiles – make it a game.

Deficiencies in current knowledge and areas for future research

The only level 1 evidence and grade A recommendations cited in this chapter relate to the use of electrophysiological testing (ABR, OAE) for screening and diagnostic assessment in infants under six months of age.¹ Other test methods are essentially descriptive, having been progressively modified, based on expert experience.^{4, 10, 22} Whilst specific elements of the test protocols have been subjected to small-scale controlled studies, for example the use of different noise stimuli in sound field testing,¹¹ the only large-scale studies available examine the feasibility of obtaining response thresholds using a test protocol, rather than its sensitivity or specificity.²² There is clearly a difficulty in performing blind controlled trials of obviously differing techniques. There are also no subject-specific definitive response thresholds available for comparison. Reliance is placed on intra- and intertest/retest reproducibility, as an indication

of accuracy.^{20, 26} Comparison of behavioural test response thresholds with subsequent pure tone audiometry thresholds cannot take account of fluctuating hearing levels during the intervening months or years.

There are therefore inherent challenges in conducting large-scale controlled trials. In the UK, emphasis has more recently been placed on establishing guidelines for good practice, promoting training and availability of equipment with the aim of improving equity of service (www.nhsp.info; www.mchas.man.ac.uk).

SEARCH STRATEGY

The references for this chapter were compiled from a Medline search using the terms deaf, hearing loss or hearing impairment and child. The World Health Organization (WHO) website (www.who.int), the NHS Newborn Hearing Screening Programme website (www.nhsp.info), the deafness and hereditary hearing loss overview website (www.geneclinics.org/profiles/deafness-overview/details) and the NHS Modernising Childrens' Hearing Aid Service website (www.psych-sci.manchester.ac.uk/mchas) were also consulted.

INTRODUCTION

This chapter focusses on the general principles of management of a moderately to profoundly deaf child. Sensorineural deafness may occur before (prelingual deafness) or after the child has acquired the ability to speak (postlingual deafness). This distinction has important implications for the child's education and management.

Earlier detection with universal neonatal screening is now practised in most developed countries. Advances in detection, genetics, imaging and treatment – including amplification and cochlear implantation – for these children have meant that new guidelines and ways of working are needed for healthcare professionals. There has also been more understanding of the deaf culture, the deaf community and their concerns with these advances. The implication of all levels and types of deafness for education has increasingly been recognized, together with the implications of managing the modern technologies in educational settings. The education of deaf children has

also been challenged with a worldwide move towards the integration of deaf children into mainstream education wherever possible.

EPIDEMIOLOGY

Approximately one child in 1000 (some 900 per year in the UK) is born with a bilateral permanent childhood hearing impairment (PCHI). This is defined as confirmed permanent bilateral hearing impairment exceeding 40 dBHL (hearing level) (average of pure tone thresholds at 0.5, 1, 2 and 4 kHz in the better hearing ear). About 60 percent of these children have a moderate (41–60 dBHL) hearing loss, while the remainder have a severe (61–80 dBHL) or profound (>81 dBHL) loss (www.who.int/pbd/deafness/hearing_impairment_grades/en/index). Hearing loss in a child may be present at birth (congenital) or may develop after birth (acquired). The prevalence of PCHI increases with age, suggesting that a further one in 1000 children develop acquired or progressive hearing

impairment.¹ The terms ‘deafness’ and ‘deaf’ in this chapter are used to cover both moderate, severe and profound hearing loss.

The WHO estimated in 2005 that there were 278 million people worldwide with bilateral moderate to profound hearing loss, of whom 62 million had deafness that began in childhood. Two-thirds of people with moderate to severe hearing impairment live in developing countries.

In the developing world, the greatest proportion of childhood hearing loss is caused by infection. This includes congenital conditions, such as rubella and cytomegalovirus, and acquired childhood infections such as mumps, measles, meningitis and chronic otitis media. In the developed world, about half of children with PCHI have a genetic cause for their deafness.

AETIOLOGY

Most children with permanent childhood hearing impairment have sensorineural hearing loss. Causes of conductive hearing loss include chronic otitis media and some rare congenital conditions, such as bilateral aural atresia. The causes of PCHI are shown in Table 69.1.

Congenital causes

GENETIC

Genetic disease results from aberrations in the coding function or processing of human DNA. In the western world, congenital sensorineural hearing loss is accounted for by genetic factors in approximately half of cases. About 77 percent of these cases of hereditary hearing loss are autosomal recessive, 22 percent are autosomal dominant and 1 percent are X-linked.² In addition, a small fraction (less than 1 percent) represents those families with mitochondrial inheritance in which the trait is passed through the maternal lineage. In general, autosomal recessive forms of hearing loss are prelingual. Autosomal dominant forms tend to present later and result in progressive, postlingual hearing loss.³

Approximately 30 percent of patients will have a pattern of additional medical anomalies such as to constitute a syndrome – syndromic hearing loss. Nonsyndromic hearing loss constitutes most cases of congenital sensorineural loss. A number of gene mutations thought to be responsible for nonsyndromic hearing loss have recently been identified. The disorder DFNB1, caused by mutations in the GJB2 gene (which encodes the protein connexin 26) and the GJB6 gene (which encodes the protein connexin 30), accounts for 50 percent of autosomal recessive nonsyndromic hearing loss. The carrier rate in the general population for a recessive deafness-causing GJB2 mutation is about one in 33.⁴

Table 69.1 Causes of permanent childhood hearing impairment.

Causes of hearing impairment		
Congenital disorders		
Genetic	Syndromic----	30%
	autosomal recessive	77%
	autosomal dominant	22%
	X-linked	1%
	Mito < 1%	
	Nonsyndromic --	70%
Nongenetic	Autosomal recessive	
	Autosomal dominant	
	X-linked	
	Mitochondrial	
	Autosomal recessive	
	Autosomal dominant	
	X-linked	
	Mitochondrial	
Congenital rubella syndrome	Cytomegalovirus	
	Congenital syphilis	
Environmental causes		
Perinatal causes	Hypoxia	
	Hyperbilirubinemia	
	Low birth weight	
Acquired disorders	Infections	Chronic otitis media
		Meningitis
		Mumps
		Measles
		AIDS
	Ototoxic drugs	
	Trauma	
	Neoplastic disease	
Idiopathic		

autosomal recessive usually prelingual
autosomal dominant usually postlingual

Syndromic sensorineural hearing loss is found in conditions such as Pendred’s syndrome, Branchio-otorenal syndrome, Usher syndrome and Wardenburg syndrome, amongst others. Conductive hearing loss is commonly encountered in Down syndrome and Treacher Collins syndrome.

NONGENETIC

Perinatal factors

In the developed world, approximately half of cases of congenital hearing loss are due to environmental factors. In previous decades, infectious agents such as rubella and cytomegalovirus were common environmental causes of hearing loss. While the frequency of such infections has dropped with the introduction of vaccines, a concomitant improvement in the survival rates of preterm babies has increased the proportion of babies with hearing loss related to perinatal events, including stays in the neonatal intensive care unit (NICU). Thus, the overall incidence of nongenetic deafness has remained approximately unchanged. Preterm and low-birth-weight infants are particularly susceptible to factors, such as hypoxia and

hyperbilirubinaemia. Davis and Wood⁵ showed that babies admitted to a neonatal intensive care unit for more than 48 hours were 10.2 (95 percent, confidence interval 4.4 – 23.7) times more likely to have a permanent hearing loss (greater than 50 dBHL in this study) than those who did not undergo intensive care. Hypoxia is associated with apnoea, difficult delivery, low Apgar scores and use of ventilation. It is known to be associated with neurodevelopmental deficits, but the exact mechanism of hypoxia-related hearing loss is unclear. Hyperbilirubinemia is an independent risk factor for sensorineural hearing loss in infants. High levels of unconjugated bilirubin cross the immature blood–brain barrier and deposit in the grey matter causing neurotoxicity. This is thought to lead to sensorineural hearing loss, which is usually permanent, although some cases may be reversed once bilirubin levels return to normal.⁶ These infants are more often than not nursed on a neonatal intensive care unit, where they may receive ototoxic drugs, such as aminoglycoside antibiotics (e.g. gentamicin, tobramycin and amikacin) and diuretics (e.g. furosemide). There is some evidence of a genetic susceptibility to the damaging effects of these drugs explaining the variability in hearing loss that affects infants treated in neonatal intensive care units.⁷

Maternal infections

Infection is still responsible for a significant proportion of acquired hearing loss, especially in developing countries, although vaccination has greatly reduced the incidence. Congenital cytomegalovirus (CMV) is the most common cause of nonhereditary sensorineural hearing loss in the developed world.^{8,9} Between 22 and 65 percent of symptomatic and 6 and 23 percent of asymptomatic children will have hearing loss following congenital CMV infection.¹⁰ It has been estimated that 12 percent of congenital sensorineural hearing loss is due to CMV infection. The hearing loss can be of delayed onset with threshold fluctuations and/or progressive loss.³

Congenital rubella syndrome (CRS) is probably the most important cause of nongenetic congenitally acquired hearing loss in countries with no rubella vaccination programme. CRS occurs when there is maternal infection with the rubella virus in the first trimester of pregnancy. It leads to a number of abnormalities in the child including deafness, ocular defects (cataracts, glaucoma), cardiovascular anomalies (patent ductus arteriosus, pulmonary artery stenosis and ventricular septal defects), central nervous system problems (microcephaly, global retardation) and characteristic skin changes (**Figure 69.1**).¹¹

The WHO has recommended vaccination against rubella (www.who.int/immunization/topics/rubella/en/index1). Two approaches have been suggested: (1) prevention of CRS only, through immunization of adolescent girls and/or women of childbearing age; or (b)

● Holder Arnold / Scott-Brown 7E

Figure 69.1 Congenital rubella with characteristic skin rash. The child was profoundly deaf. Courtesy of J Verbov, Emeritus Professor of Paediatric Dermatology, Royal Liverpool Children's Hospital, Alder Hey.

elimination of rubella, as well as CRS through universal vaccination of infants and young children (with/without mass campaigns), surveillance and assuring immunity in women of childbearing age.¹² This is the norm in most developed countries where the incidence of CRS deafness is now very rare.¹³

Syphilis is caused by the bacterium *Treponema pallidum*. It is a common infection in most of the developing world and has recently re-emerged in parts of the developed world. The main route of transmission is sexual contact, but syphilis can also be transmitted from an infected mother to her baby (congenital syphilis). Congenital infection can occur at any stage during pregnancy, but the highest likelihood of damage to the foetus is when infection occurs and is untreated during the first or second trimesters. During primary syphilis, the rate of vertical transmission in untreated women is 70–100 percent; this drops to 10–40 percent in the latent stage of the disease. Thus the poorest prognosis is for an infant infected during the first or second trimester by a 'mother in the primary or secondary stages of disease.

Hearing loss is a late feature of congenital syphilis and often appears as one of a group of signs known as 'Hutchinson's triad'. These signs include inflammation of the cornea giving it an opaque appearance, which leads to loss of vision, peg-shaped upper incisors (Hutchinson's teeth) and eighth cranial nerve deafness. Hearing loss is the least common component of Hutchinson's triad and occurs in around 3 percent of children with late congenital syphilis. It typically appears when the child is eight to ten years of age, although occasionally it may be delayed until adulthood. Onset is sudden and damage to the cranial nerve is thought to result from a persistent and ongoing inflammatory response to the infection. Loss of hearing may be unilateral or bilateral and initially involves higher frequencies, with normal conversational tones affected later.¹⁴

Congenital syphilis can be treated with high-dose penicillin, but is best prevented by identification and eradication of the infection in the mother. Prenatal screening for syphilis is commonplace in developed countries and is the main priority for prevention of the disease in developing countries.

Acquired causes

Causes of permanent acquired hearing loss include bacterial meningitis, chronic otitis media, mumps, measles, trauma and ototoxic drugs.

MENINGITIS

permanent childhood hearing impairment

The most common cause of acquired PCHI is childhood meningitis. The risk of developing significant sensorineural impairment after bacterial meningitis has been estimated at approximately 10 percent.^{15, 16, 17, 18} Early assessment of hearing after meningitis is recommended so that appropriate rehabilitation can be initiated. If cochlear implantation is necessary, this should be done with minimal delay as ossification of the cochlear duct can make implantation difficult or even impossible (see Chapter 70, Paediatric cochlear implantation).

MEASLES

Measles is a highly infectious viral illness, which presents acutely with high fever, running nose, characteristic Koplik's spots on the buccal mucosa and a distinctive generalized maculopapular rash (**Figure 69.2**). It occurs worldwide but its incidence has reduced significantly in developed countries since the introduction of an effective vaccine in 1968. It is predominantly a disease of infants and young children and occurs mostly after the age of six months. Globally, measles is the leading cause of vaccine-preventable child deaths.

Measles has been reported as a major aetiological factor for severe to profound bilateral hearing loss in deaf children. As it was known that mucous membranes all over the body were affected, the observed hearing loss was previously thought to be conductive and attributable to suppurative otitis media, chronic perforation and mastoiditis. There are reports of measles virus being found within the cochlea, thus providing the needed evidence in favour of the sensorineural component. This explains the often-reported severe and sometimes progressive/delayed sensorineural hearing loss among affected children.

The WHO and United Nations Children's Fund (UNICEF) have emphasized primary prevention of measles in its global campaign against the prevailing childhood illnesses in the developing world for several decades. Immunization for measles can be administered as a single vaccine or as the triple MMR (measles, mumps and rubella) vaccine (www.who.int/vaccines-documents/DocsPDF01/www573).

MUMPS

Mumps, caused by infection with the mumps virus, is a nonsuppurative enlargement of the salivary glands, particularly the parotids. The infection may be subclinical in up to one-third of the cases and in these the first presentation may be the appearance of complications. Sensorineural hearing loss as a result of mumps is mostly unilateral, although bilateral loss has been described. The incidence of mumps-related sensorineural hearing loss has been documented as 5/100,000.¹⁹

5 per lakhs

Mode of presentation

It has been shown that early diagnosis of PCHI has an important bearing on outcome. A landmark study has demonstrated that children whose hearing losses were identified by six months of age demonstrated significantly better receptive and expressive language skills than did children whose hearing losses were identified after the age of six months.²⁰ [***]

SCREENING

Since the recent introduction of universal neonatal screening in most developed countries, PCHI is identified mainly through this modality. However, some children with PCHI are still missed until a later age. In countries where neonatal screening has not been implemented, diagnosis is still dependent upon parental suspicion, distraction testing and preschool screening. In addition, children with progressive hearing loss may be identified by surveillance and parental/teacher suspicion. Children who develop PCHI as a result of childhood illness are usually identified by a high degree of suspicion by parents and carers and by surveillance.

Prior to the introduction of universal neonatal screening in the UK in 2001/2002, almost a quarter of children born deaf were not identified until they were over 3.5 years of age.²¹ As a result of universal neonatal screening in the UK, the median age of detection of PCHI is now ten weeks.²²

Currently in the UK, all children are screened with automated otoacoustic emissions (AOAE) as close to the time of birth as possible by a trained operator. The result of the test is either a 'pass' or 'refer'. In addition, all infants in neonatal intensive care units have automated auditory brainstem response (AABR) testing. This is because there is a proportion of children with auditory neuropathy (estimated to be up to three in 1000 in the neonatal intensive care unit) whose AOAE test would give a 'pass' result.²³ A child who does not pass the OAE screening test in both ears would go on to have AABR testing. If this too is not passed then the child is referred for further testing.

More information on screening can be found in Chapter 67, Hearing loss in preschool children: screening and surveillance.

SINGLE-SIDED DEAFNESS

Screening has also resulted in early detection of unilateral sensorineural hearing loss. In the past, unilateral hearing loss was considered to be of little consequence because speech and language presumably developed appropriately with one normal-hearing ear. The yield for permanent unilateral moderate or greater hearing loss in the Newborn Hearing Screening Programme in England is 0.64 (95 percent, CI 0.37–0.91) per 1000 screened.²² Of

course, unilateral hearing loss can also be acquired and this occurs as a result of trauma, infection, ototoxicity, metabolic disorders and surgery. Unilateral hearing loss results in an inability to hear from the direction of the deaf side, difficulty in hearing speech in noise and poor localization of sound. A review carried out in 2004 concluded that school children with unilateral hearing loss appear to have increased rates of grade failures, need additional educational assistance and may show behavioural issues in the classroom. Speech and language delays may occur in some children, but it is unclear if children 'catch up' as they grow older.²⁴

It would appear that the impact of unilateral hearing loss on the language development and educational performance varies considerably.

Current practice is that unilateral sensorineural hearing loss is investigated to identify progressive pathology or conditions that might affect the other ear, e.g. dilated vestibular aqueducts. At the time of writing, children with single-sided deafness are monitored in the UK, but not treated unless the child complains of a problem with localization or perception of speech in noise.

DELAYED PRESENTATION

The infant distraction test (IDT), which was the screening test used in the UK until recently, had been in place since the 1960s. It involved a health visitor check at the age of nine months within the community. A behavioural test was used which had neither high sensitivity nor specificity. As a result, a large number of children with normal hearing were referred for further investigations. More worryingly, a large number of children with PCHI were not being identified. There are no data available yet on how many children are detected late since the introduction of universal neonatal screening in the UK.

In countries where universal neonatal screening has not yet been established, identification of children with PCHI is still dependent on parental or teacher suspicion, locally arranged behavioural screening programmes and preschool screening. In a questionnaire-based study in Nigeria, only 12 percent of parents of a child with hearing loss suspected hearing difficulty by the age of six months. Parental suspicion occurred mostly at 12–24 months, compared with 8–14 months in developed countries. The most common mode of detection was a child's failure to respond to sound (49 percent).²⁵

PROGRESSIVE HEARING LOSS

Some children have normal hearing or only a mild loss at birth, but develop progressive hearing loss with time. A study performed in the UK just before the introduction of universal neonatal screening showed the prevalence of confirmed PCHI to be 1.07 per 1000 (95 percent confidence interval 1.03–1.12) for three-year-olds. Amongst children aged 9–16 years though, the prevalence

increased to 2.05 per 1000 (2.02–2.08). This increase in prevalence must be due to either acquired or progressive hearing loss. It is likely that a number of children have progressive hearing loss and would not necessarily be identified by neonatal or early screening.¹

Progressive hearing loss may be due to genetic or environmental causes. In some syndromes such as Pendred's syndrome, the hearing loss is typically progressive. Nonsyndromic hearing loss related to a variety of known and unknown mutations can also be fluctuant or progressive.²⁶ Some infectious causes such as congenital CMV and congenital syphilis can cause late-onset or progressive hearing loss.

This group poses a challenge, as neonatal screening will not identify them. Identification of these cases therefore is dependent upon a high degree of suspicion in children with known associated syndromes, surveillance and prompt assessment in response to parent or teacher concern.

HEARING LOSS DUE TO CHILDHOOD ILLNESS

Acquired PCHI can be caused by meningitis, viral infections such as mumps and measles, chronic otitis media, trauma or ototoxicity (streptomycin, cisplatin). Early detection of hearing loss in these groups is based upon surveillance of at-risk groups (e.g. children undergoing chemotherapy) and parent/teacher/medical staff suspicion.

THE NEWLY DIAGNOSED DEAF CHILD

Parents and healthcare professionals are faced with a series of dilemmas and challenges when it is established that a child is deaf. Parents remember with chilling clarity the day they were told their baby was deaf, and cumbersome inexpert handling of this scenario can have profound adverse effects. An experienced empathic team that works in a coordinated way with the family and can present a knowledgeable and nonpartisan approach to the various options and resources available makes for the best outcome for parents and child. Now the diagnosis is likely to take place very early in the child's life before parents have adjusted to being parents and it is even more important that time is made available for them and that they are supported in the early days.

Reactions to the diagnosis

For the majority of parents, having a child with hearing loss is completely unexpected. Parents, when confronted with a diagnosis of hearing loss in their child, go through a grieving process akin to a death experience; they have lost the expectation of the 'perfect' baby. For the parents of a child with a disability, this time frame is less rigid and

the grief can be nonfinite and last the lifespan of the child, emerging at critical points. In a survey of parental reactions to the news that their baby had failed a hearing screening test, the feelings elicited were of fear, shock, confusion, depression, frustration, anger, loneliness, sadness, blame and even aggression.²⁷

Large surveys have shown that the vast majority of parents would like to know whether their child has permanent hearing impairment as close to birth as possible.²⁸ This is now an expectation, but it places great responsibility on the professionals.

Parents will have questions regarding the development of the child, especially speech and future education needs. Many of these questions cannot be answered straight away. The parents are then bombarded with information regarding intervention and are required to make decisions often without understanding or taking in the information they have been given.

The presence of a child with hearing loss is often linked with psychosocial stress in the parents and other family members.²⁹ Once a hearing loss has been confirmed, these emotions become even more heightened. The degree of hearing loss does not seem to influence the parents' ability to cope. In fact, stress levels were found to be higher in the parents of children with less severe hearing loss.³⁰ This might be because the child may at least sometimes respond to sound, which can delay the parents' acceptance of the hearing loss and confuse the diagnosis.

The initial grief may be followed by feelings of anger, despair and helplessness as the diagnosis becomes apparent. Sadness, sorrow, even depression may occur. Parental guilt is also a feature of the reaction to the diagnosis. The expectation of having to make decisions that will hugely impact the future of their child and the amount of information from health professionals that they have to take in within a short span of time leads to confusion and sometimes insecurity.

Stress and quality of life remain factors even after the parents have come to terms with the diagnosis.

The impact on the parents of earlier diagnosis of hearing loss as a result of neonatal screening is a cause for concern. It has been suggested that such an early diagnosis of hearing loss may interfere with parental bonding with a child that is usually otherwise perfectly healthy, and which we know is vital to support the early development of communication skills, the foundations of later language development, whether spoken or signed. This concern is reflected by the experience of some parents. The risk of disturbing the parent-child relationship by early screening could be minimized by improved information and rapid and effective follow up. Young and Tattersall³¹ used a narrative approach to parents as evaluators of newborn hearing screening. They reaffirmed the excellence of screening practice but also raised new questions about how to pre-empt the experiences of the minority for whom screening will not be a satisfactory process.

Investigations

In the UK, national guidelines for investigating the aetiology of permanent childhood hearing impairment were developed by the British Association of Audiological Physicians in conjunction with the British Association of Community Doctors in Audiology (BACDA) (www.baap.org.uk/Guidelines/BAAP_guidelines_Jan_2001). It is recommended that core investigations are offered to the parents of all children with newly diagnosed bilateral sensorineural hearing loss and thresholds over 70 dB in the better ear averaged across 500, 1000, 2000 and 4000 Hz, while ‘additional’ investigations are dictated by individual circumstances and the findings of core investigations (Tables 69.2 and 69.3). Parents may not wish to pursue investigations, the results of which in many cases have no immediate impact on the management of the child, but it is essential that healthcare professionals are aware of the baseline investigations and can discuss the rationale behind various tests with parents so they can make an informed choice. There is some evidence, however, that these guidelines are not being fully implemented. This is mainly due to issues of funding and parental choice. In an audit of children diagnosed with severe or profound PCHI between 2002 and 2004, 41 percent were not offered imaging of the inner ears. A total of 47.1 percent accepted and 52.9 percent declined electrocardiograph (ECG) evaluation. A total of 70.6 percent accepted and 29.4 percent declined connexin mutations testing.³²

The aims of aetiological investigations are as follows:

- to try to answer parents who ask ‘why is my child deaf?’;
- to identify and treat medical conditions, e.g. 8th nerve aplasia, congenital infection, Jervell and Lange–Nielsen syndrome, Alport’s syndrome, neurofibromatosis type 2, Usher syndrome and vestibular hypofunction;
- to assist the family in making decisions about the most appropriate communication mode, educational placement and counselling on cochlear implantation, e.g. in 8th nerve aplasia, Usher syndrome;
- to inform genetic counselling;
- to inform epidemiological research.

The recommendation is that patients should undergo core investigations with additional investigations as dictated by the clinical scenario. [**]

CLINICAL EXAMINATION

All children with hearing loss of unknown cause should be evaluated for features associated with syndromic deafness. Important features include branchial cleft pits, cysts or fistulae, preauricular pits, telecanthus, heterochromia iridis, white forelock, pigmentary anomalies, high myopia, pigmentary retinopathy, goitre and craniofacial anomalies.

Table 69.2 Core investigations for all cases of bilateral severe to profound sensorineural hearing loss.

Investigation	
Paediatric history:	Detailed history of pregnancy delivery and postnatal period. Developmental milestones including speech and language and motor milestones, pre- and postnatal noise exposure, history of ototoxic medications, head injuries, ear disease, meningitis, viral illness and immunization status
Family history:	Deafness or risk factors associated with hearing loss in first- and second-degree relatives
Clinical examination:	Inspection and physical measurement of craniofacial region, assessment of the neck, skin and nails, limbs, chest and abdomen. Developmental examination
Audiology:	Age-appropriate assessment including tympanometry. Audiometry on first-degree relatives
Imaging:	Magnetic resonance imaging of inner ears and/or computed tomography of petrous temporal bones.
Electrocardiograph	
Urine for microscopic haematuria	
Connexin 26 and 30 mutations testing with access to clinical genetics service for counselling	
Ophthalmic assessment	
Referral to clinical geneticist	
Vestibular investigations	

AUDIOLOGY

Skilled audiological testing must be performed to assess the severity of the hearing loss and to determine whether it is conductive, sensorineural or mixed. This is discussed in detail in Chapter 68, Hearing tests in children.

IMAGING

Imaging can detect treatable pathologies such as perilymph fistula, inner ear malformations with an associated

Serological test for congenital rubella and cytomegalovirus infections
Thyroid tests
Immunology tests
Metabolic screen blood and urinalysis
Renal ultrasound
Chromosomal analysis

^aOnly used when medical indications are present.

risk of meningitis and the enlarged vestibular aqueduct. Both computed tomography (CT) and magnetic resonance imaging (MRI) can be useful. Imaging modalities and techniques are discussed in Chapter 102, Imaging in paediatric ENT.

Radiological abnormalities either on CT or MRI are found in about one-third of children with PCHI (**Figure 69.3**). On CT scans, a large vestibular aqueduct is the most common isolated finding, while cochlear dysplasia is the most common abnormality in scans showing multiple abnormalities. Other abnormal findings include lateral semicircular canal dysplasia, otic capsular lucency, small internal auditory canals and hypoplastic cochlea. MRI scans are more likely to detect abnormalities primarily involving the central nervous system.³³ There is a slightly higher yield of radiological abnormalities with increasing severity of hearing loss and a significantly higher imaging yield with unilateral sensorineural hearing loss than with bilateral.³⁴

At least 40 percent of children with large vestibular aqueduct (LVA) will develop profound sensorineural hearing loss. The identification of LVA should raise the suspicion of Pendred syndrome and thyroid abnormality. Patients with LVA are at risk for progressive deafness after minor head trauma. Identifying this anomaly influences management as it prompts a search for treatable thyroid function anomalies and parents can be counselled with respect to the dangers of incidental head trauma.³⁵

SEROLOGY

Universal neonatal screening will detect less than half of all sensorineural hearing loss caused by congenital CMV infection³⁶ as the hearing loss in a large proportion of children with congenital CMV is progressive. Laboratory testing has to be carried out in neonatal samples within three weeks of life. This presents difficulties as after three weeks of age, virus isolation could be due to acquired infection, which is not usually associated with adverse outcome. Previous studies^{9,37} have shown that dried blood spots on Guthrie cards collected at birth for the screening of metabolic disorders have proved a valuable

tool for demonstrating CMV DNA for diagnosing congenital infection after months or even years of life.

Rubella-specific IgG and IgM synthesized by the foetus are detectable at birth in CRS. However, since maternally derived rubella-specific IgG is also present in infants' sera, laboratory diagnosis of CRS is almost invariably made by detection of rubella-specific IgM responses. This response is detectable in almost 100 percent of CRS cases up to age three months with the most sensitive antibody-capture assays. The response declines progressively to less than 50 percent at 12 months and is rarely detectable after 18 months. It is therefore suggested that there is value in testing for CRS only if the deafness is identified within the first six months of life.³⁸

GENETIC SCREENING

The disorder DFNB1, caused by mutations in the GJB2 gene (which encodes the protein connexin 26) and the GJB6 gene (which encodes the protein connexin 30), accounts for 50 percent of autosomal recessive non-syndromic hearing loss. The carrier rate in the general population for a recessive deafness-causing GJB2 mutation is about one in 33. It is current practice that the families of all children with severe/profound hearing loss

are offered genetic screening for these two mutations. Establishing a molecular diagnosis of GJB2-related deafness is important clinically since these children can avoid further diagnostic tests and are not at increased risk for medical comorbidity. In general, bony abnormalities of the cochlea are not part of the deafness phenotype and developmental motor milestones and vestibular function are normal.⁴ The hearing loss associated with GJB2-related deafness can vary from mild to profound. The diagnostic yield of GJB2 screening is significantly higher in patients with severe to profound sensorineural hearing loss (SNHL) than in all other groups.³⁴ Preciado *et al.* suggested that a cost-effective approach to screening would be to test children with severe to profound SNHL with a GJB2 screen, as opposed to those with milder SNHL, who should undergo imaging as the initial testing step.³⁹

Screening for the mitochondrial aminoglycoside susceptibility gene mutation A1555G is offered to patients who have developed hearing loss following exposure to aminoglycosides, perhaps on the neonatal intensive care unit. If the gene is identified and subsequent administration of aminoglycosides restricted, then the severity of aminoglycoside-induced hearing loss can be limited. Also, as the gene is inherited from the mother, restricting the use of aminoglycosides in maternal relatives will also limit the prevalence of hearing loss caused by these drugs.⁴⁰

Numerous genes have been and continue to be identified relating to hereditary hearing loss. DNA testing can be carried out but at present in the UK, except for the connexins and the aminoglycoside susceptibility genes, routine screening is not performed.

BLOOD TESTS

Although routine blood tests such as full blood count (FBC), thyroid function tests, erythrocyte sedimentation rate (ESR), syphilitic blood tests, cholesterol and triglyceride levels, urea and electrolytes are carried out, abnormalities are rarely related to the cause of the hearing loss.³⁴

Genetic counselling

Genetic counselling is the process of providing individuals and families with information on the nature, inheritance and implications of genetic disorders to help them make informed medical and personal decisions. The parents of all children with genetic PCHI should be offered the services of a genetic counsellor; they might not be considering further children themselves, but it is important for their present children and their future plans of families of their own. These discussions are likely to be sensitive and the information needs to be shared sensitively with a counsellor present to follow up issues;

discussion of comparative statistical odds can be very confusing and misunderstandings can lead to repercussions later. When the parents of the child are themselves deaf, then there are other issues that have to be taken into consideration. Many deaf people view deafness as a distinguishing characteristic and not as a handicap, impairment or medical condition requiring a 'treatment' or 'cure', or needing to be 'prevented'. In fact, having a child with deafness may be preferred over having a child with normal hearing.⁴¹ Healthcare professionals need to be sensitive to these feelings and to have a frank discussion with parents to establish their views and aspirations.

Hereditary hearing loss may be inherited in an autosomal dominant, an autosomal recessive or an X-linked manner. Mitochondrial disorders with hearing loss also occur.

The risk to siblings and risk of inheritance can be predicted from the pattern of inheritance. However, clinical severity and disease phenotype may differ between individuals with the same mutation; thus, age of onset and/or disease progression may not be predictable (www.geneclinics.org/profiles/deafness-overview/details).

AUTOSOMAL DOMINANT HEREDITARY HEARING LOSS

Most children diagnosed as having autosomal dominant hereditary hearing loss have a deaf parent; the family history is rarely negative. However, the disorder may be the result of a *de novo* gene mutation. The proportion of cases caused by *de novo* mutations is unknown, but thought to be small.

If one of the parents has the mutant allele, the risk to siblings of inheriting the mutant allele is 50 percent. Individuals with autosomal dominant hereditary hearing loss have a 50 percent chance of transmitting the mutant allele to each child.

When neither parent has the deafness-causing mutation or clinical evidence of the disorder, it is likely that there has been a *de novo* mutation. However, possible nonmedical explanations including alternate paternity or undisclosed adoption could also be explored (www.geneclinics.org/profiles/deafness-overview/details).

AUTOSOMAL RECESSIVE HEREDITARY HEARING LOSS

The parents are obligate heterozygotes and therefore carry a single copy of a deafness-causing mutation. Heterozygotes are asymptomatic.

At conception, each sibling has a 25 percent chance of being deaf, a 50 percent chance of having normal hearing and being a carrier, and a 25 percent chance of having normal hearing and not being a carrier.

For children with GJB2-related (connexin) severe-to-profound deafness, siblings with the identical GJB2 genotype have a 91 percent chance of having severe-to-profound deafness and a 9 percent chance of having

mild-to-moderate deafness. For children with GJB2-related deafness and mild-to-moderate deafness, siblings with the identical GJB2 genotype have a 66 percent chance of having mild-to-moderate deafness and a 34 percent chance of having severe-to-profound deafness (www.geneclinics.org/profiles/deafness-overview/details).

X-LINKED HEREDITARY HEARING LOSS

In this pattern of inheritance, the recessive gene is carried on the X chromosome. Therefore, only males are affected.

If pedigree analysis reveals that the deaf male is the only individual in the family with hearing loss, several possibilities regarding his mother's carrier status need to be considered:

- he has a *de novo* deafness-causing mutation and his mother is not a carrier;
- his mother has a *de novo* deafness-causing mutation, as either: a 'germline mutation' (i.e. occurring at the time of her conception and thus present in every cell of her body); or 'germline mosaicism' (i.e. present in some of her germ cells only);
- his maternal grandmother has a *de novo* deafness-causing mutation.

A female who is a carrier has a 50 percent chance of transmitting the deafness-causing mutation with each pregnancy. Sons who inherit the mutation will be deaf; daughters who inherit the mutation are carriers and are likely to have normal hearing.

If the mother is not a carrier, the risk to siblings is low, but greater than that of the general population because of the possibility of germline mosaicism.

Males with X-linked hereditary hearing loss will pass the deafness-causing mutation to all of their daughters and none of their sons (www.geneclinics.org/profiles/deafness-overview/details).

MITOCHONDRIAL DISORDERS WITH HEARING LOSS AS A POSSIBLE FEATURE

Inheritance is via the mother who usually has the mitochondrial mutation and may or may not have symptoms. Alternatively, there may be a *de novo* mitochondrial mutation. If the mother has the mitochondrial mutation, all siblings are at risk of inheriting it. All offspring of females with a mutation are at risk of inheriting the mutation. Offspring of males with a mitochondrial DNA mutation are not at risk.

UNKNOWN DIAGNOSIS/MODE OF INHERITANCE

The subsequent offspring of a hearing couple with one deaf child and an otherwise negative family history of deafness have an 18 percent empiric probability of

deafness in future children. If the deaf child does not have DFNB1 based on molecular genetic testing of GJB2 (which codes for the protein connexin 26), the recurrence risk is 14 percent for deafness unrelated to connexin 26.

If the hearing couple is consanguineous or comes from a highly inbred community, the subsequent offspring have close to a 25 percent probability of deafness because of the high likelihood of autosomal recessive inheritance.

The offspring of a deaf person and a hearing person have a 10 percent empiric risk of deafness.

The child of a nonconsanguineous deaf couple in whom autosomal dominant deafness has been excluded has an approximately 15 percent empiric risk for deafness. However, if both parents have connexin 26-related deafness, the risk to their offspring is 100 percent. Conversely, if the couple has autosomal recessive deafness known to be caused by mutations at two different loci, the chance of deafness in their offspring is lower than that of the general population. (www.geneclinics.org/profiles/deafness-overview/details).

SUPPORT AND EDUCATION

The rationale for intervention

Deafness has a profound effect on both adults and children and can impose a heavy social and economic burden on individuals, families, communities and countries. In normally hearing children, the language of the home is acquired through the channel of hearing. For profoundly deaf children, this normal acquisition is disrupted, leading to the likelihood of communication, speech and language delay, which may result in under-achieving educationally and later in employment. Over 90 percent of deaf children are born to hearing families, where the language of the home will be a spoken language; for deaf children of deaf parents who use sign language, language will be acquired naturally through the visual route. For deaf children of deaf parents then language learning may be easier and more effective. As adults, deafness often makes it difficult to obtain, perform and keep employment. Both children and adults may suffer from social isolation as a result of deafness. There is some evidence that access to services for deafness are dependent on social class and income with those in developing countries and in the poorer sectors of society having difficulty in accessing the services they need.

The field of deafness is fraught with controversy for many years and the clinician needs to be sensitive to some contentious issues when working with parents of young deaf children. Deafness can be viewed in differing ways: as a medical condition to be 'cured', as a cultural and linguistic identity to be valued rather than 'cured' and the

educational models of deafness and models of intervention often reflect these differences. For parents of newly diagnosed deaf children these issues can be bewildering; although there are differing models of intervention and management, there is little evidence for the efficacy of one over another.⁴²

Today's technology of early diagnosis, effective hearing aids and cochlear implants emphasizes the medical model of deafness, in which the technology can be viewed as alleviating the effects of deafness and providing the opportunity for 'normal' development. For those with the traditional view of the deaf community, these developments can be seen as a threat in which sign language with its own grammar and culture will no longer have a place. In fact it may be that our present situation, offering more effective technology than ever before with better and earlier access to hearing and with a better understanding of the importance of early interaction in language development, offers opportunities to move forward from the old arguments and to offer deaf children real potential to develop spoken language, while not denying the value of sign language too. The interested reader is referred to the review by Marshark and Spencer⁴² of the historical and theoretical perspectives.

The effects of the rapidly changing technology and of our knowledge of child and language development makes it essential that the clinician keeps up to date with current thinking and practice in these areas, and works as part of a multidisciplinary team to ensure that information and discussions are up to date.

Hearing aids

Amplification in the form of hearing aids is the mainstay for the treatment of PCHI in most cases. Early audiological assessment and provision of hearing aids at the youngest possible age (as young as four weeks in some cases) makes for the best long-term outcome. Supplying, fitting and after-care of young children with hearing aids is a demanding and skilled professional task and an appropriately trained and experienced audiologist is essential.

Behind the ear (BTE) air conduction hearing aids with a soft mould, replaced at regular intervals as the child grows, are most commonly used. The ear mould can be replaced as the child's ear canal grows. The mould may need to be changed as often as monthly in the first year. Older children, where the ear canal volume is greater, may be able to use in the ear (ITE) hearing aids. The principles that govern choice of hearing aid and on-going support are covered in Chapter 239a, Hearing aids.

Children who are unable to use a mould in the ear canal due to conditions such as atresia may be considered for behind the ear hearing aids (Chapter 239a, Hearing aids). As a preliminary measure, while waiting for the

skull to mature sufficiently to enable fitting of a bone-anchored hearing aid (BAHA[®]), a Softband consisting of a microphone mounted on an elastic headband placed around the head may be used (Figure 69.4).

The management of conductive or mixed hearing loss is considered in more detail in Chapter 239b, Bone-anchored hearing aids.

Children with bilateral hearing loss should be fitted with bilateral aids unless there is a definite medical contraindication, e.g. infected ears. This gives the child binaural hearing with increased volume, better sound localization, reduction of the head shadow effect, improved speech recognition in noise, improvements in spatial balance and listening ease (www.psych-sci.manchester.ac.uk/mchas/).

In the UK, the median age at hearing aid fitting is now 16 weeks. The median delay from detection of hearing loss to provision of hearing aids is five weeks.²² The situation in the developing world is far less satisfactory; current annual production of hearing aids is estimated to meet less than 10 percent of global need (whqlibdoc.who.int/publications/2004/9241592435_eng).

Cochlear implantation has transformed the rehabilitation of severe and profoundly deaf children in healthcare systems where it is available, and is considered in detail in Chapter 70, Paediatric cochlear implantation.

The education of deaf children

The education of deaf children has long been the subject of controversy with the questions of where and how deaf children should be taught being hotly debated throughout the world. Often the debate has not been fuelled with evidence but rather by rhetoric, and decisions about the education of deaf children have often been dependent on

© Hodder Arnold / Scott-Brown 7E

Figure 69.4 Child wearing a BAHA[®] Softband. Photograph by courtesy of Cochlear Europe Ltd.

where the child lived rather than upon their needs or their parents' wishes. Interestingly, the arguments, choices and debates have taken place throughout the world, and today the advent of modern technologies for deaf children are influencing these decisions.

Traditionally, deaf children were educated in special schools, usually residential and often in isolated areas. Large schools for deaf children were established in many countries in the latter half of the nineteenth century and children were taught according to the prevailing philosophy in the school. During the second half of the twentieth century more deaf children were educated in integrated settings, i.e. with their hearing peers, supported by improved technology, such as the fitting of FM systems which enabled teachers to use a microphone to aid communication with the deaf child (Figure 69.5) (Chapter 239a, Hearing aids) coupled with the political will to include more children with disabilities in mainstream education. Now the terms 'inclusive education' and 'least restrictive environment' are used internationally and supported by the legal requirement in many developed countries for deaf children to have an individual education programme with their needs identified. The options for educational placement can be described as:

- mainstream education with varying levels of specialist support: this may be a teacher of the deaf visiting on a regular basis and/or in-class support from a nonspecialist assistant. This may support the development of spoken or sign language, and the in-class support will vary according to the needs of the child; it may be in the form of a note-taker, or an interpreter;
- a unit, resource base, or special class in a mainstream school, with specialist teaching always available; this can be a very flexible way of providing access to specialist teacher of the deaf support and the child's time in mainstream or resource class can be varied according to changing needs over time;

- a school for the deaf, which may be a day school or a residential school. The school for the deaf may have a specialist philosophy, using a sign bilingual approach or an oral approach, for example. It allows deaf children to have a peer group and to access specialist teaching, but can provide limited access to the broader world and, with small numbers, it can be difficult to provide specialist teaching in specialist subjects and to overcome these difficulties.

Whatever the educational placement of the child, it is important to ensure that the child's educational and social needs are met: medical and audiological services have the goal of improving hearing – for the educator there may be differing goals: those of literacy and numeracy and of social and emotional well-being. However, it is also vital that the technology supporting the child's access to the curriculum is used effectively; the acoustics in schools are often poor, the technology can be difficult to manage, particularly in a mainstream setting, and there may be considerable discrepancy between the child's functioning in the clinic and in school. A clinician involved in the fitting of hearing aids or implants should ensure that the child's teacher of the deaf understands the technology, can carry out simple trouble-shooting and has access to spares to ensure that the child is not without their amplification during the day. Accessories such as radio hearing aid systems (or FM) or sound field systems are increasingly common, but need to be managed in the classroom rather than in the clinic. Children and young people are unlikely to use their equipment if it is not functioning properly, and the growing complexity of the technology demands increasing competence from teachers and increasing liaison with the audiology clinic.

The other major decision that needs to be made on behalf of deaf children is that of communication mode, and whether to use a signed or oral approach. The Milan conference of 1860 concluded that the deaf were to be taught by oral means with the 'uncontestable superiority of speech over sign' and thus began a hundred years of the dominance of oral education over sign. The oral view was challenged strongly by the reports of poor linguistic and educational outcomes, for example,⁴³ and by the increasing voice of the deaf community, promoting its own culture and language.⁴⁴ Initially, this took the form of total or simultaneous communication with the use of spoken language and signed support. However, sign language has a grammar of its own and cannot be used with spoken language, and an interest in sign bilingual programmes where sign language is used independently of spoken language grew. In the UK, sign bilingualism began in the 1980s, interestingly at the same time as cochlear implantation, with its focus on spoken language. To summarize, communication choices used

● Hodder Arnold / Scott-Brown 7E

Figure 69.5 A teacher of the deaf using an FM microphone.

with deaf children can be categorized in three major groups:

1. oral/aural alone;
2. those approaches using speech and sign (total or simultaneous communication); **oral + sign**
3. sign bilingualism.⁴⁵ **sign only independently of oral**

There is some evidence that the new technologies of implantation and of earlier identification are changing some of these educational decisions and affecting educational outcomes. With regard to educational placement, Archbold *et al.*⁴⁶ found that significantly more young deaf children with implants were attending mainstream schools and fewer schools for the deaf than their peers with hearing aids. With regard to mode of communication and communication choice, spoken language is a realistic outcome from cochlear implantation for many,⁴⁷ but it is interesting to note that the use of sign language appears to be valued by both parents and young people with implants and it does not appear to be the case that early signing will impede the development of spoken language. Rather it appears to be the early development of effective communication which is important in early intervention, whether it is oral or signed.⁴⁸

Stacey *et al.*⁴⁷ showed that children with implants performed at the level of those less deaf than themselves and Thoutenhoofd,⁴⁹ in a detailed Scottish survey, found that children with implants did better than those without, particularly in mathematics. Vermeulen,⁵⁰ amongst others, has found that those with implants did better in reading than those without, although not as well as their hearing peers. Recent evidence shows that children with implants are not doing as well as their hearing peers in mainstream schools,⁵¹ indicating that although the modern technology of implantation is improving access to spoken language, there remain educational challenges to face.

Worldwide, the role of the teacher of the deaf is being challenged in these changing times. Teachers are likely to be involved with deaf children early in infancy and with their families, and require quite a different set of skills to effectively support parents and child at this vital time. The work of Yoshinaga-Itano⁵² has shown us how vital it is to intervene early in a deaf child's life. For clinicians, it means we have great responsibilities to liaise with each other, to understand each other's language and perspective and above all to listen to the parents of the children with whom we work.

In a questionnaire survey of adults who had been assessed and treated for deafness as children, it was found that both hearing level and educational environment influence the current mode of communication and use of hearing aids. Familial factors also seem to have an influence. Oral communication is a poor predictor of employment, whereas professional qualifications enhance the chances of finding a job.⁵³

KEY POINTS

- One infant per thousand is born with permanent deafness or hearing impairment that significantly affects language and social development. Another one per 1000 has a deafness that has some affect; a further one per 1000 develops permanent deafness during childhood.
- Approximately half of permanent childhood hearing impairment is caused by genetic factors.
- In the developing world, PCHI is largely a result of preventable causes.
- Delayed presentation is commonplace in areas where neonatal screening has not been introduced. Children still frequently present with delayed speech.
- Neonatal screening programmes have brought about earlier diagnosis, but some children with progressive hearing loss will not be detected unless surveillance is carried out during early childhood.
- Single-sided deafness is detected much earlier as a result of universal screening. The optimum management is unknown, but the condition is associated with significantly greater adverse effects than was previously thought.
- Improved imaging and advances in genetic testing have meant that a precise aetiological diagnosis can be made in an increasing proportion of deaf children.
- A diagnosis of deafness has profound psychological and social implications for both the parents and the child.
- Initial management is usually with hearing aids and referral for cochlear implantation if indicated.
- Educational support is an essential part of the management of a deaf child and his/her family.

Best clinical practice

- ✓ All children with PCHI should have a full history and clinical examination, with audiological testing as appropriate to the child's age. Families should be offered diagnostic testing to include imaging and genetic testing, and skilled genetic counselling. [Grade C]
- ✓ Optimum initial management is with early fitting of binaural hearing aids. [Grade C]

- ✓ If available and if indicated, referral for cochlear implantation should be early. [Grade C/D]
- ✓ Clinicians involved in the fitting of hearing aids or implants should ensure that the child's teacher of the deaf understands the technology, can carry out simple trouble-shooting and has access to spares to ensure that the child is not without their amplification during the day. [Grade C/D]
- ✓ Although the optimum management strategy for single-sided deafness is unknown, the child's teachers should be made aware of this condition. [Grade D]

Deficiencies in current knowledge and areas for future research

- Vaccination programmes, particularly for measles and rubella, will have an important influence on reducing the incidence of PCHI in the developing world.
- Hearing aid technology continues to improve. These technological improvements need to be accompanied by wider worldwide distribution and availability of hearing aids.
- Improvements in techniques for making a precise diagnosis in genetic deafness enables focussed genetic counselling and may ultimately facilitate therapeutic interventions.
- Imaging techniques continue to improve and are helping to facilitate more precise anatomical diagnosis.
- There is a need for population studies on the effect of single-sided deafness and for a rational approach to treatment and surveillance for these children.

SEARCH STRATEGY

The data in this chapter are supported by a PubMed search using the key words cochlear implantation and cochlear implants, limited to randomized controlled trials, human, children 0–18 years. The Cochrane and TRIP databases were also consulted.

INTRODUCTION

Hair cell loss is the principal cause of sensorineural deafness. Sufficient neural elements usually survive and are available for electrical stimulation enabling meaningful activation of the auditory cortex. A cochlear implant is a prosthetic device which replaces the transducer function of damaged hair cells and provide this electrical stimulation.

In 1969, William House recommended clinical use of electrical stimulation in profoundly deaf patients.³ Several were implanted and outcomes evaluated in detail. In the 1980s, commercially available devices were used in routine clinical practice. The Food and Drug Administration (FDA) approved their use in adults in 1984. Increased confidence in results obtained in adults led to more widespread paediatric implantation in the late 1980s. In 1990, the FDA approved the use of cochlear implants in children.

History

Electrical stimulation of the ear was attempted as early as the eighteenth century.¹ The modern era of cochlear implantation began with Djourno and Eyries² who inserted a device that produced awareness of sound, but no speech discrimination. Animal models were developed in the 1960s.^{3,4} Prototype implants were introduced in the early 1970s and rapid development took place over the next decade.

Current status

Almost all children with severe to profound sensorineural hearing loss may now be considered for implantation subject to the provisos outlined below. The potential candidate population of children in the UK is thus some 600 per annum. Most have congenital loss (1 in 1000 births), but a small number have acquired loss mainly due to meningitis.

The aetiology of severe congenital hearing loss is considered in Chapter 66, Molecular otology, development of the auditory system and recent advances in genetic manipulation. Genetic disorders account for more than 50 percent of all cases.

Devices

Implantation involves insertion of a receiver/stimulator into a bony recess in the squamous temporal bone. The cochlea is opened (cochleostomy) and an electrode array connected to the receiver is inserted. These constitute the internal device. The internal receiver/stimulator package has an embedded magnet to secure the transmitting coil. A microphone, microprocessor and transmitter coil (external device) is positioned by magnetic coupling over the internal device and delivers the encoded signal (Figure 70.1). receiver & electrode array = internal device

The microphone is connected to a speech processor, which digitally processes and then encodes the auditory signal. The signal is then transmitted transcutaneously to the implanted receiver/stimulator, which stimulates the surviving neural elements in the modiolus. This enables selective stimulation of the relevant segments of the surviving ganglion cell population with the tonotopically determined frequency information.

All the current cochlear implant devices used in the UK enable good auditory habilitation in most patients. There is still a significant variability in individual results. Although there are many technical differences between the implant devices in relation to speech processing and device specifications, there is no conclusive evidence

that any one implant device has performance benefits over the others.

TIMING OF IMPLANTATION

Prelingual deafness

Depending on the time of onset, deafness can be prelingual or post-lingual, i.e. occurring before or after the development of normal speech and language. The critical period for speech and language development lasts for a significant portion of the first decade of life, but is a continuum rather than a discrete event. Hence there is a transitional category that is referred to as perilingual deafness, i.e. deafness arising during acquisition of key speech and language skills. In outcome, these children are equivalent to those in the prelingual category.

Neuroplasticity (the ability of the brain to respond adaptively to behaviorally relevant stimuli) is a feature of both motor and sensory functions. If a congenitally blind child has vision restored after the first few years of life then, although the child is able to 'see' objects and different colours, they are unable to recognize them. This is referred to as cortical blindness. The same phenomenon is observed in relation to hearing and speech and language development. Where auditory input is restored to patients only after the first decade of life, they are unable to acquire normal speech and language. The existence of a critical period for language development during the first five years of life is well established.⁵ Providing auditory stimulation during this period is critical.⁶ Deafness significantly reduces language development. A normally hearing child

Figure 70.1 Implantation of a device. (a) Side view; (b) front view.

may have a vocabulary of between five and 26 thousand words by the age of five years. A profoundly deaf child of the same age typically has only 200 spoken or signed words.⁷ Developmental studies support the potential benefits of early implantation. Ryals and colleagues⁸ have demonstrated that the auditory system requires early stimulation to develop normally and that auditory deprivation may prevent development of normal frequency and place coding. Studies of animal models have shown that electrical stimulation commenced shortly after inducement of deafness enhances neural survival and may prevent changes in the central auditory system.

Animal experiments indicate that changes take place both in the brain stem and auditory cortex that produce a neurophysiological barrier to successful implantation after the 'critical period'.^{9, 10}

There is increasing evidence from functional brain imaging studies with positron emission tomography (PET) to confirm this auditory critical period. In effect, unused brain capacity is reassigned to other tasks if not hard-wired for its primary designated purpose within the first few years of life. This confirms the judgement of experienced clinicians that early implantation, probably before the age of two and possibly significantly earlier, is required to maximize the potential for normal language development in prelingually deaf children. Conversely, if a congenitally deaf child presents late, e.g. after the age of seven, it is likely that the benefit of implantation in relation to speech and language acquisition and recognition will be very limited. Many centres would therefore counsel parents against implantation.

Early implantation

The National Institutes of Health (NIH) consensus statement in 1995¹¹ advocated implantation in children after the age of two years. However, clinical practice has evolved and implantation is now being performed regularly in children below the age of two years. Implantation below the age of one year usually requires special circumstances, such as rapid obliteration of the cochlea following meningitis.

Several studies have begun to confirm the benefit in terms of speech and language outcomes for children implanted at an earlier age.^{6, 12, 13, 14, 15, 16}

Kileny *et al.*⁶ studied a group of 48 implant patients at the age of seven years and a further study involving 53 patients who were assessed three years following implantation. The study confirmed that in terms of speech recognition with monosyllables and multisyllabic words and sentences, children perform better with increased duration of use of cochlear implantation and reduced age at implantation. Children implanted at a younger age performed better than children implanted at an older age.

Harrison *et al.*¹³ reported a retrospective analysis of 70 profoundly deaf children, 78 percent of whom were

congenital. The age range of this group was 2–15 years and they achieved a five-year follow up. Several standard speech perception tasks were administered (phonetically balanced kindergarten (PBK), Glendonald auditory screening procedure (GASP), test of auditory comprehension (TAC), word intelligibility by picture identification (WIPI)). A binary partitioning algorithm was used to divide the dataset on the basis of age and implantation. This allowed the data to be divided into two age categories, those above and those below the age of 4.4 years. Analysis of speech perception performance indicated that there was a statistically significant improvement in scores in those implanted at a younger age compared with those implanted later.¹³

Govaerts *et al.*¹⁵ analyzed a retrospective longitudinal cross-sectional study of 70 paediatric cochlear implant patients and demonstrated that for children implanted after the age of four years categories of auditory performance (CAP) scores rarely reached normal. However, for patients implanted between two and four years, normal CAP scores were usually reached and two-thirds were integrated into mainstream primary schools. Implantation below the age of two years always resulted in a normal CAP score with 90 percent being integrated into mainstream preschooling. A possible bias in this study related to the fact that children implanted at a young age have normally been identified as having a significant hearing loss at a younger age and therefore received hearing aids at an earlier age. Although the numbers are not sufficiently large to avoid this source of bias, some of the children implanted at an older age had received hearing aids at an early age, but still had outcomes related to their age at implantation.¹⁵ All of these studies are cohort studies with no controls. It is extremely unlikely that a study which randomized subjects to either a prolonged hearing aid use group or cochlear implant group would be accepted by parents. So, although Yoshinaga-Itano *et al.*¹⁷ have reported early intervention of whatever kind as being beneficial to the ultimate outcome in terms of language development, a view supported by the study by Moeller,¹⁸ the precise reason for this has never been proved. The hypothesis that it may be the habilitative effort that is important in determining the positive outcomes in cochlear implant children is unlikely to be tested.

Post-lingual candidates

Post-lingual deafness in children is most frequently a consequence of meningitis or head injury. Although the duration of deafness is a factor in speech perception outcome after cochlear implantation, it is not an overriding issue. In adults with cochlear implants, the trend in most reported series indicates that the longer the duration of deafness, the poorer will be the outcome in relation to speech perception. However, most children who become

profoundly deaf after a significant period of normal language development (five to ten years) and who receive a cochlear implant will regain excellent open-set auditory-only speech discrimination skills.

ASSESSMENT

Assessment is a multiprofessional evaluation of hearing, communication ability, cochlear morphology, middle ear/mastoid status and other relevant general developmental issues.

Audiological tests

Many infants will have already undergone electrophysiological tests as part of their diagnostic assessment, usually either auditory brainstem responses (ABR) or electrocochleography (ECoChG). While these tests provide some indication of the severity of the hearing loss, behavioural testing when available is preferred as it is a test of the entire auditory pathway (not just the peripheral system and brain stem connections). Behavioural aided and unaided responses are obtained using visual reinforcement audiometry (VRA). In very young children, the level of language competency means that speech discrimination tests are not available. Therefore, audiological candidacy is informed mostly by the aided responses. The criterion adopted now by most UK centres is that if aided thresholds at frequencies above 2 kHz are greater than 50 dBA, then benefit from a cochlear implant is likely.

In older children (post-lingual deafness), standard pure tone and aided free field tests are performed, but speech discrimination tests are more critical. Assessment is similar to adults though the test material will need to be 'language-age' appropriate. An aided audiogram is a reasonable surrogate predictor of speech discrimination ability. Speech discrimination scores are performed both in the auditory-only and auditory with lip-reading modes. An auditory-only open-set sentence score of below 30 percent is generally regarded as being an indicator of likely benefit from cochlear implantation; however, some centres may implant candidates with 50 percent discrimination scores. Vestibular testing is not routinely performed on children.

Imaging

High-resolution computed tomography (CT) scanning shows the bony morphology of the cochlea and labyrinth. Congenital abnormalities include the Mondini dysplasia, common cavity deformity or a large vestibular aqueduct. The internal auditory meatus may be narrow and raise the possibility of auditory nerve aplasia. Meningitis can cause

significant obliteration of the cochlea. ^{meningitis} Ossification is usually found in the basal turn of the cochlea near the round window, but sometimes ossification is complete.

The accuracy of high-resolution CT scanning to predict patency of the cochlea is extremely variable; high-resolution magnetic resonance imaging (MRI) is regarded as being superior to CT in this respect, but it can still underestimate the degree of cochlea ossification.^{12, 19, 20, 21}

Imaging is particularly important in post-meningitic patients in confirming the presence of a fluid-filled basal turn. High resolution three-dimensional (3D) reconstructions may provide information on patency of the individual scalae. In cases where there is no auditory response, high-resolution MRI scans may demonstrate the presence of an auditory nerve. This is particularly important if a CT has demonstrated an abnormally narrow internal auditory canal (IAC).

Infants may require sedation or anaesthesia to undergo imaging and therefore it is advantageous to be able to perform MRI and CT together.

PET or functional magnetic resonance imaging (fMRI) will increasingly provide functional information in relation to persistent plasticity and in the future may provide valuable information in relation to candidacy.

Medical assessment

The trend towards decreasing implantation at a younger age means that anaesthetic and perioperative risk must be evaluated, particularly for children with complex medical conditions. Young²² found that in implanting infants less than 12 months of age there are physiological issues that require the anaesthetic risks to be considered seriously. The benefits of early surgery must be weighed against these risks. He acknowledges that there may be factors such as rapidly progressing obliteration in post-meningitis cases which may alter the risk/benefit balance, but the anaesthetic risks need to be carefully discussed as part of the informed consent process.

Neurodevelopmental issues

This is a complex area for implant teams. Candidacy has recently been extended to children with learning disabilities and other developmental problems. Outcomes are more difficult to demonstrate, but benefit in communication is achieved by some. Careful consideration is needed to assess likely benefit to hearing and to quality of life. Problems with lack of reliable reporting of auditory sensations may make devising optimum stimulation parameters difficult, and there is the risk of causing distress due to overstimulation. Some of these issues may be overcome with electrically evoked ABR response testing, now possible on the newest generation of implant devices.

PREOPERATIVE COUNSELLING

The potential implant candidate must not be looked at in isolation. Consideration should be given to the assessment of parental or care-givers attitudes, particularly the ability to assist in the delivery of an intense postoperative programme to enable the child to develop receptive and expressive oral language skills. This will include commitment to an appropriate educational environment to maximize potential. Social workers and/or psychologists may help to ensure the importance of these issues is recognized.

Following the assessment process and determination of likely benefit, the parents are counselled regarding the surgery and the habilitative management process. This will include explanation of the benefits and risks of surgery, variability of outcome and the requirement for intensive and prolonged input from the implant centre team and local professionals.

SURGERY

A low complication rate is now reported from most established centres, with a 'learning curve' in new centres.

Technique

The surgery involves several steps.

- **Incision and flap design.** Implant surgery was initially performed via a large incision. Gibson *et al.*²³ were the first to advocate a much smaller post-aural incision and by the late 1990s most surgeons had begun to adopt some version of what resembles a standard post-aural mastoidectomy incision. This reduces flap-related problems and is more acceptable to children and their parents since a large head shave is not required.²⁴ A recent survey of UK implant centres reported a flap-related complication rate of 2.4 percent in children, but that included earlier cases preformed with larger incisions.²⁵
- **Bony approach to cochlea.** A standard mastoidectomy is followed by a posterior tympanotomy preserving the chorda tympani. The round window region is visualized through a posterior tympanotomy. The scala tympani is entered via a cochleostomy anterior to the round window niche. Following electrode insertion, any space between the electrode and the cochleostomy can be sealed with soft tissue, usually fascia or muscle. There is an increasing trend in the UK towards use of a facial nerve monitor.²⁵
- **Bony recess for and fixation of receiver/stimulator.** A device-specific contoured bony recess is fashioned for the receiver/stimulator package. In children this

almost always involves exposure of the dura. Most surgeons prefer to preserve a bony island over the dura if possible. Fixation of the device can be with either absorbable or nonabsorbable sutures. Bone cement is also used for electrode fixation at the mastoid rim or posterior tympanotomy.

- **Closure and postoperative care.** Drains are rarely required. Most patients receive some form of antibiotic cover, though there is no generally accepted regime. Many patients have some form of imaging of the electrode array (most frequently via a modified Stenvers view) to confirm satisfactory position prior to discharge.

Complications

THE FACIAL NERVE

The incidence of facial nerve damage is very low. Hoffman and Cohen²⁶ reported 0.58 percent in children ($n = 1905$); in a UK series, 0.2 percent had permanent facial nerve injury.²⁵

Non-auditory stimulation, usually of the facial nerve, is relatively common following cochlear implantation, particularly in post-meningitic patients. It is thought that bony channels develop, allowing electrical stimulation of the horizontal segment of the facial nerve. Often these problems can be overcome by programming out the relevant electrodes. Care must be taken in these cases as this aberrant effect of stimulation may upset the child and lead to an aversion to device use.

Bigelow *et al.*²⁷ reported an incidence of 14 percent of some form of non-auditory or facial nerve stimulation. In a very small number of cases, if a significant number of electrodes have to be switched off, implant performance may be degraded.

MENINGITIS

There are concerns about a possible increased risk of meningitis – particularly pneumococcal – in children who have had cochlear implantation. Epidemiological studies are complicated by the fact that the cochlear implant population has a higher incidence of meningitis before cochlear implantation than the general population. A survey in the United States showed that of roughly 5000 children under the age of five who had been implanted, 300–400 had had an episode of meningitis prior to the implantation; 17 had had meningitis after implantation. This increased risk of meningitis in deaf individuals may be due to structural abnormalities such as common cavity deformity or enlarged vestibular aqueduct.²⁸

The advice from the Department of Health in the UK is that all patients who have been implanted should be offered pneumococcal vaccination. Prospective patients should be advised regarding immunization prior to

implantation. Patients who have implantation and develop otitis media or signs of other febrile illnesses should be urgently assessed by either their general practitioner or the implant centre.

DEVICE EXTRUSIONS

This is one of the most serious complications following implant surgery. Hoffman and Cohen²⁶ reported an incidence in children of 0.16 percent ($n = 1905$). Gibbin *et al.*²⁵ reported the experience of UK centres with a similar incidence of 0.25 percent.

DEVICE FAILURES

Earlier implants had various design faults, which provided some device reliability problems. Cumulative survival rates for all the devices in use in the UK are in the range of 97–99 percent.

SPECIAL SURGICAL CIRCUMSTANCES

Cochlear anatomical abnormalities

Implantation of the malformed cochlea is technically feasible.²⁹ Patients with an enlarged vestibular aqueduct or enlarged vestibule may have ‘gushers’ intraoperatively. Several authors have concluded that outcomes in terms of speech discrimination in these patients are similar to those with no structural abnormalities.

Obliterated cochlea

Ossification develops as a consequence of meningitis, temporal bone trauma and some autoimmune disorders. The basal turn of the scala tympani is most frequently affected due to the connection between the subarachnoid space with the scala tympani via the cochlear aqueduct. Scala vestibuli ossification is less common and may take place later in the ossification process.^{30, 31}

Ossification was initially thought to be a contraindication to cochlear implantation, but various surgical procedures have been developed to allow at least partial implantation in those cochleas with significant degrees of ossification. Gantz *et al.*³² described a drill-out procedure by creating a trough around the modiolus, drilling out the entire basal turn. Balkany *et al.*^{33, 34} modified this technique using an intact canal wall procedure. Steener-son *et al.*³¹ described scali vestibuli electrode insertion in which the scali vestibuli is opened anterior to the round window by drilling above the spiral ligament. The outcome in patients whose implant was inserted into the scala vestibuli was compared to matched controls who

had standard scala tympani insertion. The outcome measures including sentence recognition scores and vowel and consonant speech scores were similar in both groups. He concluded therefore that scala vestibuli insertion was an acceptable alternative to scala tympani insertion in partially obliterated cases.

Cohen and Waltzman³⁵ described partial insertion through a short inferior tunnel drilled along the basal turn. In some cases, this partial drill out will reach a patent segment of the basal turn and a full insertion is then possible.

More recently, the implant manufacturers have produced different electrode configurations to deal with the problem of the ossified cochlea.^{36, 37} A dual/split array is available; one electrode is inserted into an inferior tunnel drilled along the basal turn and the other electrode is inserted into a separate cochleostomy drilled into the superior limb of the basal turn. A compressed electrode array with an increased number of electrodes along a shorter distance is an alternative in a basal turn drill-out procedure.

Chronic suppurative otitis media and open mastoid cavities

Patients with mastoid cavities were initially considered unsuitable for implantation. However, increasing experience has led most centres to offer surgery to these patients. Various techniques are described.³⁸ Surgery is performed as a one- or two-stage procedure. In the two-stage procedure, all squamous epithelium is removed from the cavity, which is then obliterated behind a blind sac closure of the external canal. After an interval, the cochlear implant device is inserted at a second-stage operation. In the one-stage technique, the device is inserted following removal of disease and the cavity obliterated and closed. in both the procedures.

POSTOPERATIVE HABILITATION

This is a multidisciplinary effort involving audiologists, speech and language therapist and specialist educators; it begins with programming the device with stimulation parameters for the electrode array which will provide auditory perception across the speech range. In the very young, this can be assisted by electrophysiological measures which can predict the threshold and comfort levels for electrical stimulation. In older children, behavioural responses can be used to refine the implant stimulation parameters. These parameters can change over time and therefore need to be regularly confirmed at ‘programming’ sessions. The role of the speech and language therapist and specialist educators is to maximize the potential provided by the auditory input to develop speech perception and intelligibility, and thereby to permit access to the educational curriculum as fully as possible.

CONTROVERSIES IN MANAGEMENT

Implantation in older children and adolescents

The ideal age for implantation in congenitally deaf children has been discussed. The current recommendation is around or just before the age of two years. Several studies have examined the benefits of implantation in older children and adults. Waltzman *et al.*³⁹ examined the outcomes in 35 congenitally deaf children who received implants after the age of eight years and 14 congenitally deaf adults. The results indicated that there was improvement in open-set speech perception in children. Adults demonstrated improvement in mean scores for word and sentence recognition, although the improvement was not as significant as in children implanted at a younger age. Results were adversely influenced by increasing duration of deafness and older age at time of implantation.

Bilateral cochlear implantation

In the last few years, experience has grown with bilateral implantation and studies in adults report the benefits binaural hearing should provide, including sound localization and enhanced speech recognition in background noise.

Muller *et al.*⁴⁰ reported a study of nine bilaterally implanted adult patients tested for speech understanding in quiet and in noise. They were tested in three situations, left implant only, right implant only and both implants activated. The speech discrimination tests included monosyllables in quiet and sentences in noise. Results indicated higher speech scores for all subjects with bilateral stimulation. This has encouraged bilateral implantation in children and preliminary results indicate that outcomes measured by auditory perception and speech intelligibility are improved.⁴¹ Bilateral implantation will require further longitudinal evaluation of significant numbers of children in order to confirm these early reports indicating that additional benefits accrue from the second implant.

MRI following cochlear implantation

The presence of a magnet in the current implant systems has led to MRI being contraindicated in implanted patients. The devices have a removable magnet; a small incision over the posterior half of the receiver/stimulator package will allow the implanted magnet to be removed to enable MRI to be performed. This requires a small surgical procedure with the risk of introducing infection.

A recent study⁴² shows that it is possible to perform an MRI scan provided the scanner is equipped with a 1-Tesla magnet.

QUALITY OF LIFE MEASURES

Cheng *et al.*⁴³ have reported that cochlear implants in profoundly deaf children have a positive effect on quality of life at reasonable direct costs and appear to result in net savings to society.

The cost-utility of paediatric cochlear implantation was analyzed by O'Neill *et al.*⁴⁴ They concluded that it was an effective intervention with a quality adjusted life year (QALY) gain of £10,341 (\$21.00), and recommended the intervention as effective for profoundly hearing-impaired children. QALYs are a measure of the benefit of a medical intervention. The measure takes into account both quantity and quality of life generated by a healthcare intervention and is based on the number of years of life that would be added by the intervention. Each year in perfect health is assigned the value of 1.0 down to a value of 0 for death. If the extra years would not be lived in full health, for example if the patient were to lose a limb, become blind, or be confined to a wheelchair, then the extra life-years are given a value between 0 and 1 to account for this.⁴⁵

Francis *et al.*⁴⁶ reported that cochlear implantation accompanied by aural rehabilitation increases access to acoustic information of spoken language, leading to higher rates of mainstream placement in schools and lower dependence on special education support services. The cost savings that result from a decrease in the use of support services indicates an educational cost benefit of cochlear implant rehabilitation for many children. However, larger more methodologically robust studies will be required to strengthen evidence and deal with confounding variables such as socioeconomic status, cognitive function, age of diagnosis of deafness and language intervention, and the mode of communication.

Although now a decade old, the NIH consensus statement¹¹ is still the outcome of the most extensive systematic review, it concluded that:

Cochlear implantation improves communication ability in most adults with severe to profound deafness and frequently leads to positive psychological and social benefits as well. Currently, children at least two years old and adults with profound deafness are candidates for implantation. Cochlear implant candidacy should be extended to adults with severe hearing impairment and open-set sentence discrimination that is less than or equal to 30 percent in the best aided condition. Access to optimal education and (re)habilitation services is important for adults and is critical for children to maximize the benefits available from cochlear implantation.

KEY POINTS

- Cochlear implantation is a proven effective treatment for the management of severe to profound sensorineural hearing loss in children.
- All infants and children who are diagnosed as having a severe to profound congenital hearing loss should be referred urgently for assessment.
- Increasingly, implantation is undertaken between the ages of one and two years.
- The results in older children are less good, but assessment by an implant centre is still worthwhile.
- Patients in the UK are managed within a multidisciplinary team in a small number of specialized centres.
- Complication rates are low.
- Studies have confirmed the cost effectiveness of paediatric implantation.

Best clinical practice

- ✓ Any child with a hearing loss >70 dB (unaided), acquired or congenital, should be referred for assessment.
- ✓ Children with aided levels >50 dB at frequencies of 2 Hz and above should be referred to a specialist centre.
- ✓ Children with significant deafness post-meningitis should be referred urgently because of the risk of progressive obliteration of the cochlea.
- ✓ Age at implantation in the pre- or perilingual deaf has an inverse relationship to outcomes of enhanced oral communication.
- ✓ Implantation should take place in a designated centre, with experienced staff working in a multiprofessional team.

Deficiencies in current knowledge and areas for future research

- The implementation of universal neonatal hearing loss screening with resultant early intervention should lead to improved outcomes for all children with hearing loss, particularly those requiring cochlear implantation.
- Lack of RCT based evidence is a deficiency but is unlikely to be resolved due to the perceived effectiveness of implantation and therefore difficulty in recruiting to a hearing aid arm of such a trial.

SEARCH STRATEGY

The data in this chapter are supported by a search of the Guidelines databases on www.nelh.nhs.uk, the Cochrane library and TRIP databases using the key words congenital, middle ear and ossicle. This was supplemented by a PubMed search using the key words congenital and middle ear or ear, ossicle.

INTRODUCTION

Conductive hearing loss in children is usually acquired. The most common aetiology is otitis media with effusion (OME) but it may be the result of chronic otitis media (mucosal or squamous). In the presence of severe congenital deformity of the external ear, associated abnormalities of the ossicular chain are common but in isolation they are rare and often have a delayed diagnosis, particularly if unilateral.

A variety of nonossicular congenital middle ear abnormalities may also be associated with ossicular deformities. They may be symptomatic in themselves or be important aspects of other middle ear conditions and surgery. They include:

- persistent stapedia artery;
- anomalous course of the facial nerve;
- congenital perilymphatic fistula;
- high jugular bulb;
- aberrant internal carotid artery.

Definition of congenital ossicular abnormalities

Congenital ossicular fixation and defect is defined as a malformation affecting the ossicular chain, present at birth, which leads to a dysfunction of the ossicular mechanism due to immobility or discontinuity of the ossicular chain.

Major malformations involve both the tympanic cavity and the external ear (ear canal and pinna) and are described as congenital aural atresia or microtia. In association with these conditions, in either sporadic cases or as part of a syndrome such as Treacher Collins or Goldenhar, there may be a variable degree of ossicular abnormality and there may also be associated inner ear dysplasia.

Minor malformations affect the ossicular chain alone and the tympanic membrane and ear canal are normal.

CLASSIFICATION OF CONGENITAL OSSICULAR ABNORMALITIES

There have been many published classifications based on individual surgeons' series.¹ Cremers' classification

describes the largest published series of operated minor congenital ear anomalies (104 cases).² It has been modified by Tos³ and seems to be the most inclusive and descriptive of all the published schemes (**Table 71.1**).

Minor malformations are divided into four main groups, each of which may be subdivided: isolated stapes ankylosis, ankylosis with other ossicular anomaly, isolated ossicular anomaly and aplasia or severe dysplasia of the oval or round windows. [*]

INCIDENCE OF CONGENITAL OSSICULAR ABNORMALITIES

Bergström⁴ reported that out of a group of 687 children with congenital hearing loss, only eight (1.2 percent) were

found to have isolated middle ear anomalies. There is no systematic report of absolute incidence though Thringer *et al.*⁵ reported the incidence of conductive hearing loss, severe enough to require amplification, to be 0.6:1000. These cases were all bilateral. The incidence of unilateral cases is unclear.

Cremers and Teunissen's series² does provide a relative incidence with stapes ankylosis with another associated ossicular chain anomaly being the most common finding (38 percent) with isolated stapes ankylosis being the other largest group (30 percent). Isolated anomaly of the ossicular chain was found in 22 percent and aplasia or severe dysplasia of the oval or round windows in 10 percent.

In a Japanese surgical series, Hashimoto *et al.*⁶ reported a much higher rate of incudostapedial joint

Table 71.1 Cremers' classification of minor congenital anomalies of the ossicular chain in 144 operated ears (modified by Tos).

Class	Main anomaly	Subclassification	% 144 ears
1	Isolated congenital stapes ankylosis (or fixation)	a. Footplate fixation 1. Normal stapedial arch 2. Monopodial stapedial arch 3. Monocrural stapedial arch b. Stapes suprastructure fixation 1. Elongation of the pyramidal eminence 2. Stapes-pyramidal process bony bar 3. Stapes facial canal bony bar 4. Stapes-promontory wall bony bar 5. More than one bony bar	30.6
2	Stapes ankylosis associated with another congenital ossicular chain anomaly	a. Incus and/or malleus deformation or aplasia of the long process of the incus b. Bony fixations of the malleus and/or incus	38.2
3	Congenital anomaly of the ossicular chain but mobile stapes footplate	Discontinuity of the ossicular chain Aplasia of the long process of the incus Dysplasia of the long process of the incus Epitympanic fixation Malleus Anterior Superior Lateral Incus body Superior Lateral Medial Short process of the incus In incudal fossa Tympanic fixation Of the malleus handle Of the long process of the incus	15.3 6.3
4	Congenital aplasia or severe dysplasia of the oval or round window	Aplasia Dysplasia Crossing (prolapsed) facial nerve Persistent stapedial artery	6.9 2.1 0.7

defects, either in isolation or with stapes fixation, making up nearly 50 percent of cases.

The majority of Cremers' cases were sporadic though in 25 percent they were part of a recognizable congenital syndrome including branchio-oto-renal, hemifacial microsomia, Klippel-Feil, Crouzon and Pfeiffer syndromes. [**]

CLINICAL PRESENTATION OF CONGENITAL OSSICULAR ABNORMALITIES

Children with bilateral ossicular abnormalities will often present at a similar age to children with OME because of poor hearing performance and speech delay. It is not unusual that the children are managed with one or more sets of ventilation tubes before the diagnosis is made. The observation of a conductive hearing loss, normal tympanic membrane and normal middle ear pressures should lead to the general diagnosis.

INVESTIGATION OF CONGENITAL OSSICULAR ABNORMALITIES

Audiometry

There is an average threshold of approximately 50 dB, producing a flat air conduction line, with no low frequency bias as with otitis media. There is an average air-bone gap of 35 dB between 0.5 and 2 kHz, either due to Carhart's effect or because of the presence of an underlying sensorineural hearing loss. Tympanometry usually demonstrates a normal middle ear pressure with reduced compliance due to fixation of the ossicular chain.

Imaging

High resolution computed tomography (CT) scanning remains the primary imaging modality though complementary magnetic resonance imaging (MRI) studies may demonstrate associated labyrinthine and internal auditory meatal abnormalities. CT virtual endoscopy may offer a further mode of presenting the images for preoperative surgical planning though as yet it fails to image satisfactorily the stapes suprastructure.⁷

Exploratory surgery

The diagnosis may only be made during a tympanotomy, though an interesting alternative to lifting the tympanic membrane is to attempt to visualize the ossicles via Eustachian tube and middle ear endoscopy.⁸ The innate risk of damage to the ossicles and extent of view with this technique is as yet not well defined.

PRINCIPLES OF MANAGEMENT

As with all cases of hearing loss, children and adults with congenital ossicular abnormalities need to be managed with thought to their overall hearing performance and requirements.

In the presence of a bilateral moderate hearing loss due to a maximal or near maximal conductive hearing loss, some form of auditory rehabilitation should be recommended. For the majority, this will mean a conventional unilateral or bilateral air conduction hearing aid. With minor malformations there should be a stable external ear canal as a platform for amplification. If the patient develops local complications in the external ear canal, such as recurrent or chronic otitis externa, a bone-anchored hearing aid (BAHA) would be a suitable alternative. [*]

Unilateral cases are less well defined in terms of best management. In the presence of ipsilateral tinnitus, amplification may act as a tinnitus masker. A hearing aid may improve the patient's hearing performance in background noise and optimize sound localization. The positive benefits need to be weighed against the potential morbidity of a conventional hearing aid, which includes the occlusion effect, otitis externa and the body image issues involved in wearing hearing aids, particularly amongst children and adolescents.

Surgery for congenital ossicular abnormalities should only be undertaken by dedicated otologists with experience of complex middle ear reconstruction. When the diagnosis has been made in childhood, consideration for surgery should be preceded by an adequate trial of amplification. Whatever middle ear surgery is contemplated, but particularly with stapedotomy, there is a significantly higher risk of delayed sensorineural hearing loss due to sporadic episodes of acute otitis media in children under ten years of age. By this time it may be appropriate to involve the child in the decision-making process or to wait until adolescence or adulthood to allow the patient to come to their own decision regarding surgical treatment.

A preoperative CT scan would be a mandatory investigation to attempt to identify the ossicular abnormality, but also to visualize any other middle or inner ear abnormality such as an anomalous facial nerve, congenital cholesteatoma, aberrant vascular structures or labyrinthine dysplasia.

MANAGEMENT OF SPECIFIC CONGENITAL OSSICULAR ABNORMALITIES

Isolated stapes ankylosis

Tos³ subdivided Cremers' basic classification to separate stapes ankylosis into two main groups, depending on

whether the footplate or suprastructure is fixed (Table 71.1). In 20 percent of cases the suprastructure may be abnormal, with one crus being absent (**monocrural**) or there being no recognizable crura but instead a single strut (**monopodial**).⁹

Congenital stapes ankylosis at the level of the footplate was first described by Shambaugh¹⁰ in 1952. He emphasized the clinical contrast to otosclerosis, in particular that the margins of the congenitally fixed footplate and the annular ligament are difficult to visualize since the footplate bone blends into the bone of the surrounding otic capsule.

The pathological processes leading to stapes footplate fixation are unclear. Lindsey *et al.*¹¹ concluded from a temporal bone study that fixation occurs due to failure of the annular ligament to differentiate from the lamina stapedialis. This leads to continuous ossification from the otic capsule to the footplate. Nandapalan and Tos¹² argue, however, that the cause is a subsequent ossification of the already formed annular ligament, around 16 weeks of gestational age, because any arrest of development at this stage would be likely to cause a more widespread inner ear abnormality.

An ossified stapedial tendon may develop because of a failure of its precursor to form a tendon and instead become cartilaginous like the neighbouring precursor of the pyramidal eminence.¹² This subsequently becomes ossified, fixing the stapes. The other rare forms of fixation of the stapes suprastructure are probably caused by the persistence of the contact between the developing stapes and Reichert's cartilage, which is usually lost as the stapes forms.

Surgery for congenital stapes footplate fixation

Preoperative scanning may demonstrate labyrinthine dysplasia, any degree of which should alert the surgeon to an increased risk of inner ear damage. In particular, a dilated fundus of the internal auditory meatus (IAM) should be sought. This is a feature of X-chromosome-linked progressive mixed deafness with perilymphatic gusher.¹³ The dilation of the IAM is associated with a defect allowing communication of cerebrospinal fluid (CSF) with the labyrinthine, which is released through a stapedotomy and leads to a high rate of sensorineural hearing loss. The high perilymph pressure may be the cause of the apparent conductive element of the hearing loss, which may mask the principal sensorineural nature of the raised air conduction thresholds. A previously reported association with a 'patent cochlear aquaduct' has been shown to have no histological basis in temporal bone studies.¹⁴ The aquaduct is normally patent and cases of so called 'widely-patent' ducts seems to relate to a flaring on the medial aspect of the duct as it enters the

jugular foramen. There is little variation in the duct as it passes through the otic capsule.

The surgical technique is similar to otosclerotic stapes ankylosis. A common feature of congenital fixation is the presence of thick anterior and posterior crura. To reduce the risk of inner ear damage these may be vapourized with a KTP laser.¹⁵ This may also be used to aid the formation of a stapedotomy as the footplate is often thick.

Reported outcomes of surgery from specialist centres for isolated congenital fixation of the stapes nearly match the outcomes in the literature for adult series for otosclerosis, with more than 70 percent closure of the air–bone gap (ABG) to 20 dB or less.^{6,16} However, excellent results, with an ABG of less than 10 dB, seem less common than with surgery for otosclerosis.¹⁷ Rates of inner ear damage are also comparable. [**]

Surgery for stapes suprastructure fixations

In the very rare cases where the footplate is mobile but the suprastructure is fixed, removal of the bony bar can be achieved using a CO₂, argon, KTP or erbium laser or with a microdrill. Traditionally this has been achieved with a curette or by fracturing with good results.¹²

Isolated non-stapes middle ear anomalies

There is a large variety of described anomalies amongst case reports in the literature and these represent the different subclasses in Table 71.1. In addition the stapes itself, though mobile, may be dysplastic.

The surgical management is by appropriate tympanoplasty. If there is attic fixation then a separate atticotomy is necessary to expose the problem and allow surgical treatment. If there is a bony bar this can be relieved by laser, microdrill or curette. A similar approach is used with fixation of the malleus handle by an atretic plate. With the absence of the long process of the incus, an interposition prosthesis is indicated.

Stapes ankylosis associated with other deformities

The potential anomalies are as described when found in isolation. Stapedotomy is again indicated but it may be necessary to consider a mobilization of the ossicular chain if there is epitympanic fixation or a malleovestibulopexy following removal of the head of the malleus.⁶ Though surgery is difficult in cases of a deformed incus or fixations of the incus and malleus in the attic, reported results are good.¹⁷

Congenital aplasia or severe dysplasia of the oval and round windows

The stapes crura are usually poorly developed and do not reach the region of the footplate and may be embedded in the facial nerve. In such cases the course of the facial canal is often anomalous.

With such a severe abnormality preventing conduction of sound energy into the inner ear and particularly with the risk of a facial palsy with an anomalous facial nerve, auditory rehabilitation with hearing aids or a BAHA may be most appropriate. The potential surgical solutions have significant drawbacks. A fenestration procedure would leave a cavity requiring long-term care. A neo-oval window operation, in which a *de novo* entrance into the labyrinth is either drilled on the promontorial or even on the rostral side of the Fallopian canal, has a high risk of inner ear damage.²

NONOSSICULAR CONGENITAL MIDDLE EAR ABNORMALITIES

Persistent stapedial artery

The stapes forms around the stapedial artery, leading to formation of the obturator foramen. By ten weeks of development the artery atrophies, leaving a patent foramen underneath the arch of the stapes. If persistent, it arises from the petrous internal carotid artery (ICA), traverses Jacobsen's canal for a short segment, exits at the promontory, passes through the stapes obturator foramen and enters the Fallopian canal close to the cochleariform process. The persistent stapedial artery (PSA) passes anteriorly, exiting the canal at the geniculate ganglion and passes into the extradural space of the middle cranial fossa, where it gives rise to the middle meningeal artery. In the presence of a PSA, the foramen spinosum is usually absent and the ICA may have an aberrant course due to its collateral formation secondary to a segmental agenesis of the ICA.¹⁸

A PSA may present as a vascular mass within the middle ear,¹⁸ found either during otoscopic examination of the ear or during middle ear exploration, but is often asymptomatic or the cause of pulsatile tinnitus and has no relationship to conductive hearing loss.

It may also present as a chance finding during stapes surgery (Figure 71.1). It is unclear whether the discovery of a PSA during a stapedectomy indicates a congenital fixation or whether it is coincidental in cases of otosclerotic stapes ankylosis.

Traditional teaching has been that the presence of the artery is an absolute contraindication to stapedectomy, partly as it was thought that damage to the artery would lead to ischaemic damage to the facial nerve. Govaerts *et al.*,¹⁹ however, reported 12 cases, including two of their

© Hodder Arnold / Scott-Brown 7E

Figure 71.1 Finding during stapes surgery – a persistent stapedial artery (PSA).

own, in which the outcome of surgery was satisfactory. In three cases the artery was damaged or clipped without any postoperative complications. [*]

Anomalous course of the facial nerve

The Fallopian canal may show dehiscence or have an anomalous course within any part of its course within the temporal bone. This has great surgical significance and may be a hazard in all forms of tympanomastoid surgery. An abnormal course is particularly common with microtia or with dysplasia of the oval and round windows and there should be a high index of suspicion in any surgery for congenital conductive hearing loss and the use of the facial nerve monitor is highly recommended.

The Fallopian canal arises from the otic capsule and the second branchial arch and a theory of the cause of an anomalous facial nerve is a failure of fusion of the two. As there is a relatively high association with other ossicular abnormalities other than of the stapes, a local teratogenic effect may also be responsible.

Rohrt and Lorentzen²⁰ classified facial nerve displacement in the middle ear into four groups:

1. facial nerve partially obliterates the stapes footplate;
2. bifurcation of the facial nerve;
3. facial nerve rests on the footplate with deformed stapes or oval window;
4. facial nerve rests on the promontory.

Though these abnormalities are often found in association with stapes fixation, it may be normal and mobile, even in the presence of a bifurcated facial nerve (Figure 71.2).

© Hodder Arnold / Scott-Brown 7E

Figure 71.2 Stapes may be normal and mobile, even in the presence of a bifurcated facial nerve.

Congenital perilymphatic fistula

Congenital perilymphatic fistula (PLF) is an abnormal communication between the middle and inner ear. It may be associated with:

- microfissures around the oval and round windows;
- labyrinthine or IAM dysplasia.

The diagnosis is controversial as there is no reliable preoperative test which identifies the condition and management is based on the suggestive diagnosis of a child presenting with progressive or fluctuating sensorineural hearing loss, possibly associated with vertigo. Weber *et al.*²¹ define the intraoperative diagnosis as being based on the identification of clear fluid which reaccumulates with anaesthetic Valsalva or Trendelenburg manoeuvre. Beta-transferrin positive samples are consistent with CSF being a constituent of the leak and this will be a feature of some but not all cases of PLF, usually associated with labyrinthine or IAM dysplasia. This is not a real-time test during the surgical procedure and is very specific but not very sensitive for PLF, which may not contain CSF.²²

In view of the difficulties of diagnosis, Weber *et al.*²¹ suggest the policy of packing temporalis muscle around the oval and round windows in all suspected cases. This is based on the observation that packing does not seem to cause any significant complications (such as a subsequent conductive hearing loss) and he argues that it may be beneficial despite no confirmation of a PLF. In his series of 160 ears with suspected PLF there was a greater than 90 percent rate of stabilization or improvement in hearing in both PLF positive and negative cases, though he acknowledges that in other series there is a similar outcome in nearly half of cases without packing. [**]

High jugular bulb

A high jugular bulb (HJB) is usually asymptomatic and discovered as an incidental finding on otoscopy or during middle ear surgery. It can cause heavy bleeding from accidental puncture while lifting a tympanomeatal flap or even inserting a ventilation tube.

The jugular bulb can be defined as 'high' if it reaches the level of the inferior bony annulus and is often covered by thin bone or is dehiscant. In the presence of a plethoric mass within the tympanic cavity, the differential diagnosis will include HJB, aberrant ICA, a PSA and a glomus tympanicum tumour.

An HJB can be associated with hearing loss. If it includes a medial portion impinging on the cochlear or vestibular aquaduct, a connection with vestibular symptoms and a sensorineural hearing loss has been suggested. There may be a more direct association with a conductive hearing²³ loss due to interference with the ossicles, contact with the tympanic membrane and obstruction of the round window niche.

Major surgery to occlude or re-route an HJB is unlikely to be justified by symptoms alone, though there are occasional reports of intrusive pulsatile tinnitus associated with an HJB. It is possible to consider endovascular occlusion in the rare case of persistent haemorrhage, when tympanic cavity surgery is contraindicated.²⁴

Aberrant internal carotid artery

This may be associated with other vascular abnormalities such as a PSA and likewise present as a vascular middle ear mass. Associated symptoms include pulsatile tinnitus, which may be objective, and hearing loss. In approximately 20 percent of cases it is bilateral.²⁵

An aberrant ICA is an important differential diagnosis of a glomus tympanicum tumour, which can be resolved by CT scanning. Brisk bleeding, hemiparesis, aphasia, deafness, Horner syndrome and intractable vertigo may result if the vessel is unintentionally injured.²⁵

KEY POINTS

- Congenital abnormalities of the middle ear may occur in association with major malformations such as microtia.
- Isolated malformations are rare but include anomalies of the ossicular chain and the middle ear vasculature.
- Diagnostic delay is common. Deafness due to ossicular pathology is often misdiagnosed as otitis media with effusion. It is not unusual for children to have repeated ventilation tubes before the correct diagnosis is made.

Best clinical practice

- ✓ Unless deafness is bilateral management can be conservative. [Grade D]
- ✓ If there is bilateral hearing loss, auditory rehabilitation will be required. [Grade D]
- ✓ Surgery is difficult with uncertain outcomes and best considered only by those with specific training and experience. [Grade D]
- ✓ Surgery may be best deferred until children can participate in the process of informed consent. [Grade D]

Deficiencies in current knowledge and areas for future research

- The incidence, aetiology and pathogenesis of congenital ossicular abnormalities is poorly understood.
- The role of otoendoscopy in the diagnosis and management of these conditions needs to be better defined.
- Developments in middle-ear implantation may render corrective surgery almost redundant.

SEARCH STRATEGY

Different search strategies were used for each section of this chapter, as follows:

DEFINITION AND AETIO-PATHOLOGY OF OTITIS MEDIA WITH EFFUSION

Premedline and Medline search using the key word otitis media or otitis media with effusion; and allergy, cleft palate, Down's syndrome, Eustachian tube, histology, microbiology, pathology, Turner's syndrome, gastro-oesophageal reflux or GERD or GORD.

EPIDEMIOLOGY

Medline was searched using the terms otitis media or otitis media with effusion and prevalence, and epidemiology.

DIAGNOSIS

Medline was searched using the terms otitis media or otitis media with effusion and sensitivity or sensitivity and specificity.

OUTCOMES OF CHILDHOOD OTITIS MEDIA WITH EFFUSION

Medline was searched using the key words otitis media or otitis media with effusion; and speech and language, and behaviour, and balance and/or equilibrium, and quality of life.

MANAGEMENT

Premedline and Medline were searched using the key words otitis media and/or otitis media with effusion; and adenoidectomy, antibiotics, carboxymethylcysteine, hearing aids, and homeopathy. Abstracts were reviewed to identify papers with the highest levels of evidence. These were then read and evaluated.

DEFINITION OF OTITIS MEDIA WITH EFFUSION

Otitis media with effusion (OME) is the chronic accumulation of mucus within the middle ear and

sometimes the mastoid air cell system. The time that the fluid has to be present for the condition to be chronic is usually taken as 12 weeks.¹ [*] In children, OME usually presents because of the associated hearing

impairment and sometimes with a preceding history of illness and otalgia consequent on an episode of acute otitis media.

Many synonyms have been and are used for this condition. The general public frequently refer to it as 'glue ear'. Medical terms that are no longer in common usage, because of debate about their appropriateness or tendency to cause confusion, include **serous otitis media**, **secretory otitis media** and **chronic nonpurulent otitis media**.

In many children, OME is preceded by an episode of acute otitis media with otalgia and fever. This is particularly so in younger children because of their greater propensity to upper respiratory tract infections. In the majority of children, acute otitis media is considered to have been triggered by a viral upper respiratory tract infection that damages the epithelium of the Eustachian tube, resulting in retention of middle ear fluid. These secretions then become **secondarily infected** with bacteria – acute otitis media. Once the infection has resolved, it can take time for the epithelium to recover. Hence, OME will be present temporarily in many children after an episode of acute otitis media. However, many children with OME have no recent history suggestive of acute otitis media, albeit they may have had an upper respiratory tract viral infection. This damages the Eustachian tube epithelium with resultant retention of middle ear fluid, which in these children does not become secondarily infected.

AETIO-PATHOLOGY

Histology

The ciliated, pseudostratified columnar epithelium of the respiratory tract extends up the Eustachian tube as far as the anterior part of the middle ear cavity (**Figure 72.1**). These cells are capable of producing mucus. In addition there are goblet cells and mucus secreting glands. OME is primarily caused by an inflammation of this epithelium in the Eustachian tube and hypotympanum. The histology has been well described from biopsy specimens of the middle ear mucosa^{3,4} and from temporal bone sections.⁵ Once OME has become established, the normal, flat cuboidal middle ear and mastoid mucosa is patchily replaced by thickened pseudostratified mucus-secreting epithelium with varying degrees of specialization, such as the development of cilia. Goblet cells are frequently present and sometimes mucus-secreting glands are formed. The ciliary lining would appear to be less efficient at moving the secretions into the nasopharynx than normal.⁶ [***] The submucosa is oedematous and inflamed with dilated blood vessels and an increased number of macrophages, plasma cells and lymphocytes (**Figure 72.2**).

Figure 72.1 Extent of respiratory-type mucosa within the middle ear represented by the percentage of ciliated mucus-secreting cells per unit area. A, antrum; ET, Eustachian tube; H, hypotympanum; M, mastoid; P, promontory. Redrawn from Ref. 2.

CHARACTERISTICS OF THE EFFUSION

What is frequently debated is the origin of the middle ear fluid in OME. In surgical practice, the fluid is usually characterized by its consistency as being either serous or mucoid. This is obviously a gross simplification of the situation. There will be a full spectrum of fluid types made up of a mixture of the secretions of the epithelial cells, the goblet cells and the mucus glands along with the inflammatory transudate/exudate which comes through the intracellular spaces from the inflamed submucosa. Considerable research time has been spent on analyzing the concentrations of various molecules in middle ear effusions in an attempt to draw conclusions as to why they are there and where they come from. The main finding is that it is the mucins that come from the secretions that are responsible for the variable viscosity of the middle ear fluids.⁷ [*]

Bacteriology

Table 72.1 shows the percentage of ears that had a positive bacteriological culture of a middle ear aspirate of OME fluid (more than two months duration) in children with a wide age spectrum.⁸ [***] No pathogens were cultured from fluid that had been present for at least six months. The incidence of pathogens was higher in younger children (less than two years) and in those with recurrent upper respiratory infections and recurrent attacks of acute otitis media.

Eustachian tube dysfunction

Inevitably, if the epithelium of the Eustachian tube is inflamed, becomes oedematous and loses its cilia, then it

Figure 72.2 Otitis media with effusion – cross section through the temporal bone. Minimal effusion remains post-mortem, but the mucosa (arrowed) of the middle ear over the promontory and in the facial recess is hypertrophied, hyperaemic and slightly polypoid. The bony Eustachian tube (ET) is patent. C, cochlea; EAC, external auditory canal (meatus); ME, middle ear. (Collection MEEI).

will dysfunction as an aerator of the middle ear. Though a viral upper respiratory tract infection is probably the most common cause of damage to the Eustachian tube epithelium, there are other potential reasons. It may be secondary to an allergic reaction (see Allergy) or pollutants such as cigarette smoke. It may be secondary to chronic nasopharyngeal infection in the adenoidal tissue or gastro-oesophageal reflux. It will be rare that abnormal Eustachian tube dysfunction will be due to a disorder of the palatine muscles. The exception to this will be children with a cleft palate.

Craniofacial abnormalities

Children with a cleft palate, even if repaired, have deficient palatine muscles and resultant poor Eustachian tube function. As a consequence, OME is virtually universal in infants with a cleft palate and surgical repair of their clefts does not seem to influence the incidence. As the child ages the incidence falls, but there are no cohort studies to give age-related data, though the overall

incidence is at least 40 percent. The disease is extremely persistent and in the longer term gives rise to a high incidence of chronic otitis media of at least 20 percent in ten year olds.⁹ [***] Whether this is helped or made worse by surgery is debated. Children with a bifid uvula do not appear to have a higher incidence of OME.¹⁰ [***]

Children with Down or Turner syndrome are also more likely to have OME, but reliable data on the incidence are not available.

Allergy

The majority of children with OME do not have allergic symptoms of their upper and lower respiratory tracts or skin. The question is whether allergic children are more likely to develop OME and if they do so whether their OME is more protracted than normal. Comparing the incidence of allergy in OME children attending a particular clinic with the population incidence can be subject to referral bias. This is evident by the considerable variation in the incidence of allergy reported from different clinics that cannot be accounted for by different methods of diagnosis.

Population cohorts of children under the age of two years that have investigated atopy/allergy as a risk factor for the development of OME have not found allergy to be significant even in a univariate analysis.^{11, 12} [***] Similar cohort studies in older children are not available. However, three prospective studies of children covering all ages with OME that looked for risk factors for persistence did not find atopy/allergy to be a significant factor.^{13, 14, 15, 16, 17} [***]

It must be concluded that the best evidence does not support allergy as a risk factor for the occurrence or persistence of OME. [***]

Gastro-oesophageal reflux

Radiographic evidence of gastro-oesophageal reflux is common in children and its relevance to many conditions has perhaps been overestimated. However, initial reports on the biochemical analysis of middle ear fluid in OME suggest that pepsin is present in a high proportion of effusions (approximately 80 percent).¹⁸ [*]

Subsequent prospective reports on children with OME or recurrent otitis media would raise doubts as to whether pepsin is causative as of 14 children with bilateral effusions positive pepsin assays were only present bilaterally in seven children.¹⁹ [**]

Further prospective investigations are required to clarify the role, if any, of gastro-oesophageal reflux in childhood OME.

EPIDEMIOLOGY

The epidemiology of OME has been extensively studied in many countries, but mainly in Denmark, Finland, the Netherlands, the United States of America and the United Kingdom. The majority are studies of cohorts of children followed up at regular intervals from birth to two or three years of age. As such, there are many level 2 evidence studies to report from, it being usually impracticable to perform randomized controlled epidemiological trials (see below under Outcomes of childhood OME). No recent systematic review has been identified, that of Daly²⁰ being based on early publications where the study design and method of analysis tends to be poorer than in subsequent papers. Hence, the papers quoted here were mainly published after 1990.

Prevalence

The prevalence of a condition is the proportion of a population that has a condition at any one time. Such data are useful as an indicator of the potential clinical workload. The incidence of a condition measures the chances of developing the condition. In childhood OME, the main determinants of the prevalence are the age of the child and the season of the year.

ASSOCIATION WITH AGE

Zielhuis *et al.*²¹ [***] reviewed a total of 23 studies that all used tympanometry as one of the diagnostic instruments to give age-specific prevalence rates up to ten years of age (Figure 72.3). The prevalence is bimodal with the first and largest peak of approximately 20 percent at two years of age. This is the age at which many children first attend a playgroup or nursery school. Thereafter the prevalence declines, but there is a second peak of approximately

16 percent at around five years of age when most children start attending a primary school. In Figure 72.3 there are few data points below the age of two years and hence the exact location of the first peak is liable to errors of interpretation. A more recent study, using a diagnostic algorithm of tympanometry and otoscopy, suggest that the peak is more likely to be around one year of age (Figure 72.4).²³ [***] The proportion of unilateral to bilateral OME shown in this figure is discussed below under

Figure 72.3 The prevalence of otitis media with effusion at different ages with 95 percent confidence intervals (CI). Chart shows the combined results of 23 studies. Redrawn from Ref. 21, with permission.

Figure 72.4 Prevalence rates of unilateral, bilateral and uni- or bilateral OME in a group of healthy-born infants from birth to two years of age. Redrawn from Ref. 22, with permission.

Duration and recurrence of episodes in children under the age of three years.

By the age of seven to eight years, the prevalence falls, but is still material around 5 percent depending on season (Table 72.2).²⁴

ASSOCIATION WITH SEASON OF THE YEAR

In temperate climates, the effect of the season on the prevalence of OME has been recognized for many years, with around twice as many children being diagnosed with OME in the winter as opposed to the summer months.^{25, 26, 27, 28} [***] Why there is a difference could be due to many factors. The most likely are the increased frequency of upper respiratory and ear infections in the winter and the greater chance of passing them on between children because of the closer contact in cold weather and when they are not on holiday. Indeed if these factors are controlled for, in some studies the effect of season is no longer as evident,²⁹ [***] but not in others.^{30, 31} [***]

Evidence from nontemperate countries might help to sort out season from upper respiratory tract infections and contact with other children. The prevalence of OME in white children in Mediterranean^{32, 33} [**] and subtropical countries^{34, 35} [**] does not appear to be different overall from those in temperate countries. Unfortunately, no seasonal analysis was made. However, a comparison was made³⁶ [***] of the prevalence in a northern tropical country (Vietnam) in the dry (3 percent of ears in April) and the rainy seasons (11 percent of ears in December which is humid and chilly). Their second peak of prevalence was not at five to six years of age, but at over eight years, when many children start work in the paddy fields. More such studies would be of value.

Risk factors for occurrence of OME under three years of age

Interpreting the literature on risk factors for the occurrence of OME is complicated by the need to use a rapid, simple, readily applicable method for diagnosing OME. Serial tympanometry is the method most

Table 72.2 Prevalence of type B tympanogram by age and season using school term as a surrogate.

Age (years)	Autumn (%)	Spring (%)	Summer (%)	Mean (%)
5	13	20	17	17
6	9	13	8	10
7	4	10	7	7
8	0	6	6	6
All ages	9	14	10	

Reprinted from Ref. 24, with permission.

commonly used with a type B tympanogram being considered diagnostic of OME. Whilst this may be a sensitive categorization in the diagnosis of the majority of cases, it is not that specific in that there are a good number of false positives (see below under Diagnosis).

The risk factors studied are not the same in all studies. The inclusion of the most important ones is vital. This requires *a priori* knowledge of what these are likely to be. The same factors are unlikely to apply to all age groups, for example, breast feeding. The factors that predict occurrence of OME are not necessarily those that predict the persistence of OME.

Many studies have too few subjects with a particular characteristic, e.g. not many five-year-old children do not go to school.

A multivariate or a comparable analysis of the data is required to control for confounding variables, for example, if low socioeconomic group is a factor is it the small house, the number of siblings, the smoking, the junk food or the lack of a maternal university education and a car that makes the difference? It is unlikely to be all of them.

Surgery in some children complicates the analysis and complicates its interpretation.

It is likely that the risk factors for the occurrence of unilateral and bilateral OME will be the same. This has been confirmed by Engel *et al.*³¹ [***] Again, on *a priori* grounds, the risk factors for persistence of OME are likely to be different. This is particularly because of the introduction of disease-related factors such as the degree of the associated hearing impairment that could be related to persistence.

Knowledge of risk factors can be of interest in helping to understand why some individuals are more prone to suffer from a condition than others. In a specific individual, the risk of developing the condition can be estimated and any risk factors present modified, if this is possible.

Episodes of acute otitis media

In the age group most studied, i.e. 0–2 years, recurrent episodes of acute otitis media are frequent and this is likely to be the largest single factor for developing OME. Each acute episode has been reported to increase the odds ratio of developing OME by 12 (CI 6, 25) but this risk no longer remains after three months.¹¹ [***] Hence the risk factors for acute otitis media, such as prematurity, frequent upper respiratory infections and nonbreast-feeding, will apply in such children.²³ Studies of children in this age group that do not include the frequency of acute otitis media (AOM) must be considered less than optimal.

Unfortunately there is no evidence that management of acute otitis media, and in particular with antibiotics, makes any difference to the chances of having subsequent OME.³⁷ [***]

Contact with other children at home and at playgroups

Table 72.3²⁹ [***] shows the risk factors in addition to AOM in a multivariate analysis for the occurrence of OME. This confirms the increasing effect of age up to two years of age, but also the effect of having siblings and a family history of them having OME. In another study that otoscopically examined family members of children with OME, rather than rely on historical reports, 32 percent of siblings and 19 percent of parents were also classified as otoscopically affected.³⁸ [**]

Other multivariate studies have suggested that in addition to the number of siblings, attendance for daycare with four or more other children up to 3.5 years of age can double the risk (CI 1, 3).³⁰ [***] This risk has been confirmed by others.¹² [**]

Some have advocated that the number of children in daycare settings could be reduced to lessen this risk, but for most parents availability, convenience and cost are limiting determinants.

Hereditability

In a same sex twin/triplet prospective cohort study, Casselbrandt *et al.*³⁹ [***] looked at sets where the zygosity was known. In children who had OME during the first two years of life, there was greater concordance in monozygotic sets in the number and duration of OME episodes than in dizygotic sets. The magnitude of the effect of heredity in comparison to other risk factors for OME was not investigated.

Race

Whether the prevalence of OME is different in different races requires control for many other factors. When factors including socioeconomic group and child contacts are controlled for in a multivariate analysis, the prevalence in black children is no different from white children.⁴⁰ [***] Chinese children may have a lower prevalence, but a multifactorial analysis has not been reported.³⁵ [**]

Table 72.3 Risk factors significant in a multivariate model for OME under two years of age.

Risk factor	Category	OR	95% CI
AOM	Yes/No	1.6	1.2, 2.1
Previous AOM	Yes/No	1.7	1.2, 2.4
Age	Increase per month	1.0	1.0, 1.0
No. of siblings	Increase per sibling	1.6	1.3, 2.0
OME family history	Yes/No	1.4	1.1, 1.7

Reprinted from Ref. 29, with permission.

It must be concluded that at present there is insufficient evidence to examine any effect of race, apart from black and white where no difference has been shown.

Gender

Some multivariate studies report the risk of developing OME to be no different in boys and girls.^{30, 31, 41} Some report a higher risk in boys^{11, 38} and others a higher risk in girls.²⁹

It must be concluded that there is likely to be little difference, if any, in the risk for boys compared to girls.

Smoking

For public health reasons, parental smoking has frequently been reported as a risk factor for the occurrence of OME. However, in multivariate analysis when other factors have been controlled for, no effect of parental smoking is detected³¹ [***] or it is present for smokers of up to 20 cigarettes per day, but the risk reduces if it is more than 20 cigarettes per day.³⁰ [***]

The conclusion must be that, in comparison to the other material risk factors for the occurrence of OME in children under the age of two years, the effect of parental smoking must be negligible. [***]

Risk factors for occurrence in children older than three years

No literature has been identified that reports a multi-factorial analysis of risk factors in children older than three years of age. However, episodes of acute otitis media are likely to be less important because of its lower prevalence in this age group.

Duration and recurrence of episodes in children under the age of three years

The natural history of the duration, recovery and recurrence of OME in 1328 children from one to two years of age is shown by ear in Figure 72.5.⁴² [***] The distribution of the duration of episodes is very skewed; the median duration of OME was three months or less, but the 95th percentile was at 12 months. Fifty percent of affected ears had resolved after three months. However, around 50 percent of the ears that resolved had a further episode.

What happens in individual infants rather than in ears has been documented by Paradise *et al.*⁴⁰ [***] In a large cohort (n = 2253) followed up from 2 months of age to 6, 12, 24 months of age, 49, 79 and 91 percent respectively had at least one episode of OME.

Figure 72.5 Natural history of OME ($n = 1217$ ears). Shaded areas indicate the presence of OME by episode of occurrence. The breadth of the hatched areas indicates the duration of the episode in various proportions of the total sample of ears. Redrawn from Ref. 42, with permission.

Hogan *et al.*⁴³ [***] followed up 95 full-term infants monthly for three years. The infants fell into three groups. The majority (65 percent) had OME at less than a third of monthly visits. Of the other 35 percent with OME at more than one visit, half of them had OME in one or both ears for more than 18 (50 percent) of their first 36 months of life. Though the mean duration of OME was longer in those with a propensity for developing OME (unilateral six weeks; bilateral ten weeks), the main difference was time between episodes. On average this was longer in children who had less OME (every 31 weeks compared with every 11 weeks).

Overall, infants were twice as likely to develop unilateral as opposed to bilateral OME. One month later, in infants with a unilateral effusion, the majority (50 percent) had resolved, a minority (20 percent) had become bilateral and the other 30 percent remained unilateral. In those with bilateral effusions at the start, one month later the majority (60 percent) remained bilateral. In the others (40 percent), bilateral resolution was more frequent than unilateral resolution (in a ratio of 3:1).

Duration and recurrence of episodes in children older than three years

A cohort of 856 British children, aged five to eight years was screened three times a year (approximately every four months) for three successive years to study the prevalence and natural history of OME defined by a type B tympanogram.²⁴ [***] Table 72.2 confirms the already reported age and season effect. There was no gender effect. The proportion of unilateral to bilateral OME was equal.

In a subsample of 67 ears with OME, the resolution rates at 4, 8 and 12 months were 52, 78 and 91 percent, respectively. The overall recurrence rate was low (7 percent).

A more detailed monthly study of seven-year-old Danish pupils ($n = 387$) reported the mean overall duration of an ear episode to be 1.8 months with 12 percent lasting more than 6 months.⁴⁴ [***] Ears first diagnosed to have OME between September and February persisted longer than those first diagnosed between March and August.

Risk factors for persistence

Three studies have been identified that have followed up children to identify risk factors that might be used to predict those that are more likely to have persistent bilateral OME. One study was carried out in primary care and followed up children who were six months or older for three months.¹³ [***] Another study was of children aged between three and seven years referred from primary care with suspected OME and seen at secondary care on average 13 weeks later.¹⁵ [***] The third study was of children of the same age identified at secondary care to have bilateral OME with an associated hearing impairment in both ears of at least 20 dB hearing loss (HL). These children were followed up for three months to identify those in whom the OME persisted bilaterally with the same degree of impairment.^{14, 16, 17} [***]

In these three studies, which all followed up the children for three months, the persistence rates of bilateral OME were 56, 35 and 51 percent, respectively. All studies identified the second half of the year (July–December) as a major risk factor with odds ratios of between 2 and 3. In primary care, whether a child has frequent or upper respiratory symptoms at the time of assessment is also an important determinant of persistence. In secondary care, the degree of associated hearing impairment predicted persistence. The only factor that might have an influence and has the potential to be modified was whether or not

the mother smoked and this was a significant multivariate factor in the secondary care study.¹⁵ [***]

In all three studies, the magnitude of the effect of any factor singly or in combination was insufficient to predict with certainty those likely to persist or resolve.

Clinical applicability of best epidemiological evidence

The prevalence of OME in childhood is age dependent, with two peaks in the distribution; one centred around one to two years of age and the other around three to seven years of age. [***]

In temperate countries, twice as many children have OME in the winter as opposed to the summer. The increased frequency of upper respiratory infections and close contact with other children during the winter months contribute to this association. [***]

Under three years of age, episodes of acute otitis media, contact with other children and heredity are factors that increase the risk of occurrence. No easily modifiable factors in the age group have been identified. [***]

Under three years of age, unilateral OME is twice as common as bilateral OME. Those with a propensity to develop OME have more frequent episodes rather than longer episodes. Bilateral OME is more likely to persist than unilateral OME. Therefore, most effort should be expended on children with bilateral OME. [***]

In primary care, children with bilateral OME and a history of upper respiratory infections are more likely to persist. In secondary care, children with bilateral OME seen in the second half of the year (July–December) with a hearing impairment of 30 dB HL in both ears are more likely to persist. [***]

None of the factors for persistence singly or in combination are sufficient to negate a requirement for watchful waiting before considering surgery. [***]

DIAGNOSIS

The initial diagnosis in most cases of childhood OME will be by otoscopy, the examiner having been alerted to the possibility by ear or hearing problems. The otoscopic appearances of OME are extremely variable and take experience to reliably detect, but can be aided by the use of a pneumatic otoscope. Hence, in many children a confirmatory method would be helpful. In some ears it will not be possible to see the tympanic membrane because of wax and again an alternative way of diagnosing OME without needing to remove the wax is helpful. The investigations available will be those that are used. In primary care this may be tympanometry and occasionally audiometry. In secondary care, both these investigations should be readily available.

Reference gold standard

In most diagnostic situations, the reference gold standard as to whether OME is present or not has to be by some other investigation. In addition, the ears that are being used as the controls are important to define. Ears that have recently had an episode of OME are likely to be different from ears that have never had OME.

Because of its availability and semi-objective nature, tympanometry is perhaps the most common reference standard used. In children who are being operated on for OME, the surgical finding of middle ear fluid can be the reference standard. Unfortunately, the surgical series has to have an undesirable 'dry tap' rate in order to calculate the ability of the investigation to detect ears that do not have fluid. Even the surgical findings are prone to error as the absence of OME may be due to the anaesthetic gases aerating the middle ear before the myringotomy is performed.

History

Though this will often initiate the assessment and be an indicator of previous problems, it is not a reliable indicator of the current presence of OME or the degree of hearing impairment. Several level 1 evidence papers support this statement. In particular, in a cohort study of 216 children followed from birth to 27 months of age at three-monthly intervals, the sensitivity of parental report of current OME and hearing impairment was poor.⁴⁵ The lack of correlation between parent report of hearing and the current pure-tone thresholds has been further illustrated by Stewart *et al.*⁴⁶ (Figure 72.6) [****] In this figure there is no correlation whatsoever between parental reports of their child's hearing and the child's hearing thresholds.

As might be expected if an infant's parents give a history of ear problems, recurrent upper respiratory infections, mouth breathing and snoring, such a child is more likely to

Figure 72.6 Parental perception of hearing loss (from 1 = definitely no to 5 = definitely yes) versus the actual hearing thresholds in the better ear, $n = 84$ children. Redrawn from Ref. 46, with permission.

have recurrent OME in the future than if there is no such history.²³ [**] It remains to be investigated whether children with such a history merit monitoring.

Diagnostic tools

OTOSCOPY

Unfortunately the otoscopic appearances of OME are extremely varied. **Figures 72.7, 72.8, 72.9, 72.10, 72.11, 72.12 and 72.13** are some examples of what can be seen. Not included are ears with residual fluid following acute otitis media which would add additional variety, particularly in abnormalities of thickness and inflammation of the pars tensa. In such ears, the tympanic membrane may also be bulging rather than retracted.

The otoscopic findings in OME are mainly different combinations of retraction of the pars tensa and variations in its colour. Retractions may be evident by indrawing of the handle of the malleus (**Figures 72.8, 72.9, 72.10, 72.11, 72.12 and 72.13**) or the presence of a neo-annular fold (particularly evident in **Figure 72.10**, but also in **Figures 72.7, 72.8, 72.9, 72.11, 72.14, 72.15**).

Figure 72.7 Otitis media with effusion (left). Malleus handle in normal position.

© Hodder Arnold / Scott-Brown 7E

Figure 72.8 Otitis media with effusion (left). Malleus handle slightly retracted.

In some ears the retractions may be more localized than others (in **Figures 72.8 and 72.12** there is a Sade grade 3 retraction to the promontory). In **Figure 72.10**, the pars tensa retraction is particularly evident inferiorly.

Colour changes can be more yellow (**Figure 72.11**), more blue (**Figure 72.15**) or just clear (**Figure 72.7**).

Figure 72.13 Air bubbles in otitis media with effusion (left).

Figure 72.14 Left tympanic membrane in otitis media with effusion showing clear colour.

Fluid levels (Figure 72.12) or air bubbles (Figure 72.13) are relatively uncommon.

In some children, otoscopy may not be practicable because the view is obscured by wax. This occurs in approximately 10 percent of ears (Trial of Alternative Regimens of Glue Ear Treatment: TARGET, unpublished data). Whether it is necessary to remove the wax is

Figure 72.15 Left tympanic membrane in otitis media with effusion showing bluish colour.

doubtful. In secondary care, tympanometry and audiometry will usually be practicable and provide sufficient information to allow decisions to be made.

Pneumatic otoscopy

This can be carried out with a closed system in a hand-held otoscope or with a Siegle's pneumatic speculum, viewed with headlight illumination or microscope. Though acceptable to most children, the inability to gain a seal with the available speculum can occur in up to 20 percent of children aged over 18 months.⁴⁷ [***] If the tympanic membrane is seen to move, the lack of a seal is irrelevant as the middle ear is obviously aerated. The problem arises when no movement is seen and air escape is evident. Most reports of the sensitivity and specificity of pneumatic otoscopy do not include such children, nor do they include children in whom the tympanic membrane could not be visualized.

Simulated otoscopy using static videos has been compared with simulated pneumatic otoscopy using dynamic videos to compare their accuracy.⁴⁸ [****] The 'true' middle ear status was determined in 'most ears by tympanometry and myringotomy data'. Overall, there was a relative improvement of 26 percent in the overall score of trainees and consultants with the addition of pneumatic otoscopy. This improvement was greater for the consultants than for the trainees. Whether the results of this simulated study can be generalized to the clinical situation remains to be reported. In practice, many clinicians use pneumatic otoscopy when they have doubts as to whether there is OME rather than routinely.

Studies that compare pneumatic otoscopy with tympanometry are available, but studies that compare pneumatic otoscopy with the findings at surgery are chosen as the type of study to report because they are a better reference standard (Table 72.4). The sensitivity of pneumatic otoscopy carried out by trained specialists ranges from 85 to 93 percent and its specificity from 71 to 89 percent. These calculations omit children in whom pneumatic otoscopy was not possible (up to 20 percent of

Table 72.4 Sensitivity (Sens), specificity (Spec), positive predictive (PPV) and negative predictive values (NPV) of otoscopy in the detection of OME with surgical findings as the reference standard.

Ears in which the tympanic membrane could not be visualized or a seal obtained are not included.

children). If they were to be included, the sensitivities and specificities would alter dramatically. The sensitivity and specificity of pneumatic otoscopy, even where practicable, would be markedly poorer in practitioners whose skills have not been validated.⁵³

Over the years, American clinical practice guidelines have strongly advocated the use of pneumatic otoscopy as the primary diagnostic method for OME.^{54, 55, 56} It is certainly to be recommended to those in primary care where the examiners are perhaps less experienced than specialists who also will have access to additional methods of assessment, including tympanometry and audiometry.

Video otoscopy

Video recordings of otoscopy, including pneumatic otoscopy, can be documented and used to monitor changes with time. It can also be used for teaching and research purposes.

FREE-FIELD VOICE TESTING

In primary care, audiometry is seldom available, particularly for younger children. Under these circumstances, the practitioner could perform free-field voice testing of hearing. Though not reported in a primary care setting, in those over the age of three years the sensitivity of modifications of the voice test (e.g. use of pictures to point at or two-syllable words) is 80–96 percent and the specificity is 90–98 percent.⁵⁷ [****] Unfortunately, these satisfactory levels are unlikely to be achieved when carried out by less experienced examiners in a primary-care setting.

TYMPANOMETRY

Tympanometry with an impedance meter (see Chapter 232, Psychoacoustic audiometry) has been advocated since the 1970s as a reliable method of detecting OME. Since then, there have been many publications on its use as a screening instrument using otoscopy as the reference standard. Its role as a confirmatory test has also been

assessed in secondary care using otoscopy, pure-tone audiometry or surgical findings as the reference standard.

Though an acoustic seal is sometimes difficult to achieve, bilateral tympanograms should be obtainable in the majority (98 percent) of children between the ages of 3.5 and 7 years,⁵⁸ in a slightly lower percentage (90–94 percent) of infants 2–11 months of age^{59, 60} and 78–88 percent of infants 12–24 months of age are included.⁶⁰

Tympanograms can be classified in multiple ways, the simplest being peaked/no-peaked, usually with the additional subclassification of peaked tympanograms depending on the pressure at which the peak is recorded. Numerical evaluation of various parameters^{61, 62} has also been advocated. These have the scientific advantages of being able to be analyzed in multiple different ways to produce ROC (receiver operating characteristic) curves. They have the disadvantage of being more difficult to apply in comparison to visually scanning the tympanogram for a peak and noting the pressure at that peak.

Peaked versus flat (non-peaked) tympanograms

The classification most commonly used is that of Jerger⁶³ modified by Zielhaus *et al.*²¹ which uses compliance and pressure as the numerical parameters. The classification can be presented in many ways; visually as examples (e.g. Orchik *et al.*⁶⁴), in a summary figure as in **Figure 72.16** or in **Table 72.5**. Analyzing papers with the findings at myringotomy (soon after tympanometry) as the reference ‘gold’ standard, suggest that a type B tympanogram is frequently associated with OME, a type A is infrequently associated with OME and a type C falls in between (**Table 72.6**). This study⁶⁴ is particularly informative because

the amount of middle ear fluid is quantified. Unfortunately, in this study type C tympanograms were not subcategorized as type C₁ and C₂.

Taking a variety of level 1 evidence studies (Table 72.7), a type B tympanogram compared with all other types of tympanogram has a sensitivity of between 56 and 73 percent and a specificity of between 50 and 98 percent in detecting OME confirmed surgically. Compared with all other types, a type B plus C₂ has a sensitivity of between 73 and 99 percent and a specificity of between 40 and 74 percent (Table 72.8). [****] Why there is such a range of values can only be partly explained by the differing proportion of ears with OME and the fact that the anaesthetic can itself aerate the middle ear giving a ‘false’ dry tap.

Pittsburgh algorithm

Table 72.9⁶² [****] shows the sensitivity and specificity of various tympanometric measures, including the gradient, which is taken alongside acoustic reflexes (see Acoustic reflexes) appears to give good positive and negative predictive values. Unfortunately, no comparison of this algorithm is made with the easier to apply peak/no-peak distinction.

Tympanoscopes

Tympanometry can also be performed with a hand-held otoscope that automatically prints out the results. Compared with the more complicated, scientific impedance bridge, these have the advantage of portability and lower cost. Hence, they are commonly advocated for use in primary care. In such a setting and with training,^{66, 67} if a type B tympanogram is classified with a type C₂ tympanogram, the sensitivity and specificity (100 and 75 percent) are comparable to conventional methods.^{68, 69} Using a type B tympanogram alone to diagnose OME gave poor sensitivity and specificity and is not recommended.

TYMPANOMETRY IN COMBINATION WITH OTOSCOPY

The results of otoscopy can either be in agreement or disagreement with tympanometry. If in agreement, their diagnostic value can be assessed against the findings at myringotomy.⁵⁰ [****] Thus, when otoscopy suggests OME and is associated with a type B tympanogram, the

Sassen <i>et al.</i> ⁶⁵	73	99	91	74	97

combined sensitivity is 98 percent. When otoscopy suggests no OME and is combined with a type A tympanogram, the specificity is 98 percent. However, in this study the findings were in agreement in only 44 percent of ears. In the other 66 percent, where the results are not in agreement, another indicator of OME such as audiometry would be required.

ACOUSTIC REFLEXES

Two papers^{70, 71} [****] showed that the results of measuring the acoustic reflexes in association with classification of tympanometry as peaked/non-peaked substantially lowered its specificity whilst adding little to the sensitivity. Such testing is therefore not advocated if this classification is used. On the other hand, if the Pittsburgh algorithm is used it would appear to add value.⁷⁰ [****]

EUSTACHIAN TUBE FUNCTION TESTS

Reliably assessing Eustachian tube function requires a method that does not depend on a child’s ability to perform a task. It also has to be applicable when the

Table 72.9 Sensitivity, specificity and predictive values of various criteria using acoustic emittance measures for the diagnosis of MEE, as determined at myringotomy, in ears with a history of chronic or recurrent otitis media ($n = 111$).

tympanic membrane is intact rather than just when a ventilating tube is in place. Sonotubometry is such a method, but needs to be improved further for it to be clinically applicable.⁷²

ACOUSTIC REFLECTOMETRY

This is performed with a hand-held acoustic otoscope that does not require a seal. It is moved around whilst emitting a sound of 80 dB A over a frequency range. The amount of sound reflected back is recorded and analyzed in various ways. Unfortunately, the sensitivity and specificity of the test is poorer than tympanometry when pneumatic otoscopy or the surgical findings are used as the reference standards.^{73, 74, 75} [***]

AUDIOMETRY

In secondary care, audiometric assessment of the hearing is mandatory in all children referred with a suspected persistent hearing impairment, irrespective as to whether OME is diagnosed at the time. If OME is diagnosed then the laterality and severity of the impairment will dictate management. If there is no OME and if the air-conduction thresholds are elevated, bone-conduction thresholds will detect the 1 percent of children with previously undiagnosed congenital, sensorineural impairments.⁷⁶ [**]

The method used to assess the hearing thresholds depends on the equipment available, the age of the child and the assessor's preference.⁷⁷ In essence, it can be performed binaurally free-field or monaurally with headphones. Tones or speech can be presented and the method of response can be by turning to the sound source or by performing a task, which can range from doing something with a toy, to raising a hand or pointing at an object or picture. Conventional air- and bone-conduction

testing is the preferred method as it tests each ear separately and can quantify any conductive component present. In children over 3.5 years of age, air- and bone-conduction thresholds are obtainable in the majority of children (95 and 92 percent, respectively) on the first occasion.⁷⁸ [**] Age is the main determinant of whether thresholds are obtainable, rather than the method of audiometry. Even if the child's concentration is poor, the results on average are only 5 dB poorer and can still be used to guide management.⁷⁸ [**]

Air–bone gap

The presence of an air–bone gap of at least 10 dB is a poor predictor of concurrent OME. Of children referred with a history of OME, 80 percent (1234 of 1551 children) will have an air–bone gap of > 10 dB, but only 32 percent will have otoscopic evidence of OME associated with a type B or C₂ tympanogram (MRC (Medical Research Council) Multicentre Otitis Media Study Group, unpublished data). Using findings at myringotomy as the reference standard, 37 percent (28 of 75) of ears with an air–bone gap of greater than 10 dB had a dry tap. It was only when the air–bone gap was greater than 30 dB was the dry tap rate reduced to 4 percent (1 of 27).⁷⁹ [***] The most likely reason for the air–bone gap being such a poor predictor is that children studied prospectively with OME will have a small residual conductive impairment after otoscopic and tympanometric resolution of their OME (personal communication). [***]

Carhart notch in the bone-conduction thresholds

As with any pure conductive impairment, one would expect OME to be associated with a Carhart notch in the bone-conduction thresholds around 2 kHz. By definition, the notch has to be 10 dB or greater between 0.5 and 4 kHz as any lesser dips could be due to test/retest error.

As such, accurate bone-conduction thresholds are required and this may be problematic in younger children. Notches are reported to be present in 48 percent of children with OME whose mean age was nine years.⁸⁰ [**] In those able to perform the audiometry, the positive predictive value of a Carhart notch in diagnosing fluid at myringotomy was 97 percent and the negative predictive value was 87 percent.⁷⁹ [**]

Ideal diagnostic strategy for OME

The ideal strategy for the diagnosis of childhood OME should be applicable to the majority of children being assessed. This rules out myringotomy and means that it has to be based on any combination of otoscopy, tympanometry and audiometry.

The first thing to consider is the percentage of children in whom one of these investigations is not possible. In the TARGET study (unpublished data), at the first visit to a specialist clinic of children with suspected OME aged between 3.25 and 7 years, it was not possible in both ears to obtain tympanometry in 1.6 percent, air-conduction thresholds in 3 percent, bone-conduction thresholds in 6 percent and otoscopy in 9 percent of children. The ability to assess the hearing thresholds was age related, ranging from 12 percent in three year olds to 11 percent in seven year olds. The inability to perform otoscopy in such a high proportion of children is partly because aural toilet to visualize the tympanic membrane was not enforced, but this is probably the usual practice of most clinicians for children in this age group.

Otoscopy should be attempted in all children not just to diagnose OME, but also acute and chronic otitis media. Pneumatic otoscopy can be of added value where there is uncertainty. In those with OME on otoscopy, audiometry is required to help determine management. Thus, in such children, tympanometry is probably only a confirmatory investigation. In those in whom the tympanic membrane cannot be visualized or the findings are uncertain, then tympanometry is essential. In those with a type B or C₂ tympanogram, audiometry will detect those with a bilateral hearing impairment of 20 dB or greater that merit follow up. [Grade D] Unfortunately, a review article of the methods of diagnosing OME⁸¹ does not address the question of whether the diagnostic method was practicable and what difference that would make to the comparisons they make. If they were to have done so, they might have proposed the above strategy rather than the use of pneumatic otoscopy.

Assessment of hearing

This is important to assess not just for the diagnostic reasons stated above, but in secondary care the current hearing thresholds are the main determinant as to management.

HISTORY

Unfortunately, reliance cannot be placed on parental report of the current hearing, though it may reflect the hearing in the past (see under Diagnosis; and History above).

AUDIOMETRY

Routine audiometric testing of the hearing of every child with OME seen at secondary care is recommended, as the associated hearing impairment can vary enormously from negligible to moderately severe (see Outcomes of childhood OME below).

TYMPANOMETRY AS A SCREEN FOR AUDIOMETRY

Having excluded a sensorineural impairment by audiometry at a child's first visit, at subsequent visits tympanometry can be used as a screen to identify those most likely to have a material hearing impairment associated with their OME. This was first proposed by Dempster and McKenzie.⁸² [****] Since then, others have examined this possibility in more detail using different audiometric cut-offs.^{58,71} [****] The results are not materially different between papers, but the later publication⁵⁸ has analyzed a greater variety of outcomes and cut-offs (Table 72.10). Thus, for example, taking 25 dB HL in the better ear as the level requiring detection, limiting audiometry to those with a bilateral type B reduces the workload by 50 percent, but will detect 90 percent of such impaired children. Limiting audiometry to those with bilateral type B or C₂ tympanograms reduces the workload to 69 percent of the sample, yet 95 percent of the impaired children will be detected.

Tympanometry can be particularly helpful if resources are limited in choosing children for more time-consuming audiometry. This should only be done once a coexisting sensorineural impairment has been excluded. [****]

OTHER CLINICAL EXAMINATIONS

What other examination is undertaken depends on whether there are any other nonotological symptoms, such as recurrent sore throats, blocked nose and snoring.

POPULATION SCREENING FOR OME

As OME is highly prevalent in the childhood population and is frequently asymptomatic, some have suggested that universal screening so that early treatment could be implemented. A Cochrane review⁸³ identified three trials where a population was screened and those with OME were then randomized to ventilation tubes or watchful waiting. No benefit was identified on language development or behaviour, the outcomes that one might hope

would benefit from early intervention. Population screening is thus not considered to be efficacious at present. [Grade A]

OUTCOMES OF CHILDHOOD OME

Natural history

As discussed earlier (see above under Epidemiology), the majority of epidemiological studies are point prevalence studies of a cohort of children at different times rather than longitudinal studies of specific children over time. There are considerably fewer data on the natural history in individual children available, this being the information most relevant to clinical practice.

As children with bilateral OME are more likely to have more severe outcomes, studies that report such children are those that are concentrated upon. Hogan *et al.*⁴³ [***] found that in children under three years of age with a propensity to have bilateral OME, the effusions lasted on average ten weeks, albeit the children were likely to have a further episode within 11 weeks.

Older children between the ages of 3.25 and seven years have been studied extensively in the UK MRC-funded

TARGET study. A total of 3831 children of this age were referred from primary care because of suspected OME. When screened at the trial clinic, only 34 percent (Table 72.11) satisfied the criterion for further study of having bilateral OME associated with a hearing impairment of at least 20 dB HL in both ears.^{14,16,17} [***] This cohort underwent a 12-week watchful waiting period, following which 49 percent of children no longer met the bilateral OME hearing criterion. That is, only 51 percent persisted. At that stage, children with persistent OME were randomized and in those who had nonspecific medical management, three months later only 49 percent were persistent.⁸⁴ [****] It was only three months later that a group of children was identified that could be truly considered to have persistent bilateral OME with a hearing.

To summarize the above data, of the children aged 3.25–7 years referred to secondary care with bilateral OME, if they waited 13 weeks to be seen, underwent a watchful waiting period of three months and then waited a further three months for surgery, by then in 92 percent of them the hearing impairment associated with their OME will have resolved (Table 72.11). Thus, even in secondary care, the vast majority of children with bilateral OME resolve spontaneously over a nine-month period, albeit the OME might recur.

Table 72.10 Sensitivity, specificity and positive predictive value (PPV) as percentages for tympanometry in all children in seven centres.

	% of sample	Type B + B tym versus others			Type B + B or B + C ₂ tym versus others			Type B + B or B + C ₂ or C ₂ + C ₂ tym versus others

Table 72.11 Natural resolution of OME in children (*n* = 3831) referred to otolaryngology from primary care (GP). Persistence is defined as bilateral OME associated with hearing ≥ 20 dB HL in both ears.

Wait	Wait time (months)	Total wait	% persistence	% persistence of original cohort
GP to otorhinolaryngologist	3	3	34	34
Otorhinolaryngologist watchful wait	3	6	51	17
Nonsurgical cases	3	9	49	8
Nonsurgical cases	3	12	89	7

Reprinted from Ref. 14, with permission.

As might be expected if a less strict definition of what constitutes persistence is taken, such as not having an associated requirement for the degree of hearing impairment, the resolution rates by ear of chronic OME are materially lower; 19, 25, 31 and 33 percent at 3, 6, 12 and 24 months, respectively.⁸⁵ [****]

Outcomes

OTOPATHOLOGY

To answer the question, ‘does OME cause pars flaccida and tensa retractions that can progress to a cholesteatoma?’ would require a cohort of children with documented OME to be followed up and compared with a cohort that do not have OME. Ideally the OME cohort would have no effective therapy for their OME, including the insertion of ventilation tubes as these themselves might cause pathology.

The best alternative evidence is from a large cohort (*n* = 964) of children who were screened for OME every three months between the ages of two and four years and were otoscopically reassessed when they were seven or eight years of age.⁸⁶ [***] The children were classified as:

- never OME (never a type B tympanogram);
- persistent OME/no surgery (type B tympanogram on at least two consecutive visits);
- transient OME/no surgery (type B tympanograms that were not consecutive);
- OME surgery (those with OME that had ventilation tubes inserted; 60 percent had only one tube inserted).

Table 72.12 shows the otoscopic sequel in these four groups of children. What one is primarily looking for is a dose–response effect, albeit the OME surgery group would be the most severe group and include any additive effect of ventilation tubes. There is a clear dose–response effect for attic retractions. This is, therefore, a disease effect. There is also a dose–response effect for tympanosclerosis and atrophy of the pars tensa, but with a particularly large increase in the ventilation tube group.

Hence, these are most likely to be disease effects, but with an increased risk following the insertion of ventilation tubes. No dose–response effect is apparent for retractions of the pars tensa. The high incidence (14 percent) of this in the OME surgery group can therefore be mainly attributed to the ventilation tubes.

It is concluded [***] that attic retractions are an OME disease effect with an incidence of approximately 14 percent in the most severe children. What proportion of these retractions progress to cholesteatoma is not known. There is no evidence that the risk of attic retraction is altered by the insertion of ventilation tubes.

Tympanosclerosis and atrophy of the pars tensa are OME disease effects, the risk of which is increased by the insertion of ventilation tubes to > 45 percent and around 70 percent, respectively.

Long-term pars tensa retractions are more likely caused by the insertion of ventilation tubes than by the disease process itself with an incidence of 15 percent.

CONDUCTIVE HEARING IMPAIRMENT

The hearing impairment associated with OME varies greatly. Table 72.13 shows the percentage of OME children aged between 2 and 12 years with confirmed, bilateral OME who have various pure-tone air-conduction averages in their better hearing ear. Overall, the mean threshold in the better ear was 21 dB HL (s.d. 10), but in 54 percent of those with bilateral OME the pure-tone average in the better ear was better than 20 dB HL.⁸⁷ [***] The mean threshold in the poorer hearing ears was 31 dB HL (s.d. 13). The speech reception or speech awareness thresholds in infants in this study were of a similar distribution. This suggests that the majority of children with bilateral OME have an insufficient hearing impairment to be materially disabling. This paper also reports a group of children with unilateral OME. In them the mean threshold in the better ear was 11 dB HL (s.d. 7) and 23 dB HL (s.d. 10) in the poorer ear.

Coincidentally, ‘normal’ children in this age group on average do not have ‘normal’ thresholds, the mean

Table 72.12 Otopathologic sequelae at seven to eight years of age in four groups of right ears.

OME persistence groups	Tympanosclerosis %	Atrophy %	Retractions pars tensa % stage ≥ 2	Attic retraction % stage ≥ 2

air-conduction thresholds in three- to six-year-old children being 3 dB HL.^{88, 89} [***]

Though it might be expected that the viscosity of the middle ear fluid would be a determinant of the hearing, it would not appear to be so. In particular, there is no difference in the hearing levels in ears with serous fluid compared with those with mucoid fluid.⁹⁰ [***]

HEARING DISABILITY SECONDARY TO CONDUCTIVE IMPAIRMENT

The main method of assessing a child’s hearing disability is by questioning the parents. Four of the nine questions in the MRC Reported Hearing Disability (RHD) questionnaire are sufficient to predict the overall disability (Table 72.14) (personal communication). [***]

Many hold that audiometric measures such as speech-in-noise would be a superior way to measure disability rather than using the pure-tone thresholds. If this were to be the case, such a measure in a specific child might more likely reflect the detrimental effect of OME and predict their likely benefit of management. Research in this area is ongoing.

Sensorineural hearing impairment

There is no evidence to suggest that OME is associated with a sensorineural hearing impairment in the short term.⁷⁸ [***]

Long-term hearing impairment

There is now considerable evidence that following the otoscopic and tympanometric resolution of fluid, ears that have had OME still have a small residual conductive impairment in the order of 10 dB HL (personal communication). [****] The reason for this is not known, but is likely to be due to ossicular chain immobility caused by some residual fluid or mucosal oedema around them.

Table 72.14 Four questions that predict a child’s hearing disability associated with OME.

Question	Response	Weighting
How would you describe your child’s hearing?	Normal	0
	Slightly below normal	0.4
	Poor	0.6
	Very poor	0.6

Unpublished data.

In a cohort followed from birth to 18 years of age, those who had had otitis media (acute and with effusion) had air-conduction thresholds that were 4 dB on average poorer than those that had not had otitis media.⁹¹ [***] Their bone-conduction thresholds were also 2 dB poorer. Whether these poorer thresholds are a disease effect or the result of surgery has yet to be elucidated.

High frequency sensorineural damage above 8 kHz has also been reported in a case series of children with OME who had been operated on and followed up for between three and five years.⁹² [**]

SPEECH AND LANGUAGE

The development of normal speech and language in a child depends on many interrelated factors, the age of the child being the major factor, but the ethnic background and the degree of interfamily communication, particularly by the mother, are important. Any hearing impairment a child might have due to their OME obviously interplays with these factors.

Assessment of speech and language is complicated by it having many components, including speech reception, speech and sound production, expressive language and cognitive understanding. When a parent expresses

concern regarding their child's speech and language, this can be partly investigated by comparing the child's performance with standard milestones. Thus, at 18 months they would be expected to have a vocabulary of ten words with meaning. More formal objective assessments can be undertaken for each of the components of speech and language and related to the results in normal age-matched controls.

Total bilateral loss of hearing during the first few years of life will obviously have a profound effect on speech and development. Whether the usually intermittent, mild to moderate conductive impairment that can be associated with otitis media with effusion in the first two to three years of life makes an impact has been extensively studied.⁹³ [****] Prospective cohort studies do indeed suggest that there is an impact of otitis media that is related to the number of days with bilateral fluid during the first two to three years of life. However, follow up of these children when they are seven to eight years of age suggests that by then the children have caught up with their nonaffected peers.⁹⁴ [***] Thus, overall, the data would suggest at most a mild effect on speech production and reception in early childhood,^{93,95} that is not modified by surgical intervention (see Surgery) and spontaneously resolves with age.

COGNITION

The factors that interplay and influence a child's intellectual development are even more complex than those that affect speech and language development. Many objective measures are available with age-related 'normal' values, but whether these are affected by a child having had OME is difficult to determine. Cohorts of children can be grouped as to how much OME they have had and this is correlated to a particular outcome, having controlled for demographic and environmental factors. Any effect of OME that has been identified occurs early in a child's academic development, around the ages of three to four years, and has been minor compared with the demographic and environmental ones. Any effect corrects itself with time and is no longer detectable once the child is seven or eight years of age.^{96,97,98} [***]

BEHAVIOUR

Abnormalities of behaviour can be reported in questionnaires by the parents or by the teachers. These can be analyzed to give a global behaviour score or be broken down into various components of behaviour. These vary between questionnaires. Thus, the Rutter score⁹⁹ can be broken down into antisocial, neurotic, hyperactive and inattentive behaviour. The MRC Behaviour Questionnaire can be broken down into anxiety, aggressive, context-related and social immaturity components. Many factors influence a child's behaviour which have to be controlled for before calculating the effect of the hearing impairment associated with OME.

Whether this is the case has been best reported in OME children being randomized in randomized controlled trials (RCT). Fifty-five percent of three-year-old children with bilateral, three-month persistent OME have abnormal overall Rutter scores. This compares with 10–15 percent of unselected three year olds.¹⁰⁰ [***] The overall behaviour scores in children aged between three and seven years with three-month persistent bilateral OME, associated with a hearing impairment of at least 20 dB HL in both ears, is 0.6 s.d. poorer (i.e. moderately) than the population scores (MRC Otitis Media Study Group, unpublished data). There is some evidence that even when a child has reached the age of 15 years, they have still poorer behaviour than non-OME children, particularly in the inattentive and hyperactive aspects.¹⁰¹ [***]

BALANCE

Around 30 percent of parents of children with OME report that they are clumsy, often imbalanced and can fall. These symptoms would appear to be more common than in non-OME children.¹⁰² [***] The pathophysiology as to why OME might cause such symptoms is difficult to understand. However, laboratory assessments of balance suggest that these are abnormal in children with a history of OME,¹⁰³ [***] but the clinical significance and relation to symptoms is unclear. It is highly likely that if they are due to vestibular dysfunction they will compensate naturally with time. There are reports that laboratory assessments improve after surgery, but these observations are uncontrolled.¹⁰⁴ [**] Improvement in such tests is also likely to occur with practice and is an alternative reason for the improvements reported.

It must be concluded that at present there is insufficient knowledge and understanding to guide the assessment and management of balance symptoms in childhood OME.

QUALITY OF LIFE

Because there are so many potential outcomes that might be attributed to a child having a mild to moderate hearing impairment due to OME, it would be helpful if an overall OME disease score could be calculated. Two such disease-specific 'otitis media' quality of life questionnaires are available. The OME-6 covers physical suffering, hearing loss, speech impairment, emotional distress, activity limitations and caregiver concern and is applicable to two-month to 12-year-old children with OME or recurrent AOM. This has been shown to improve in children who have had ventilation tubes inserted, but because of the lack of a control group it is not possible to conclude that surgery was beneficial.^{105,106} [**] There is also some concern that the OME-6 does not relate to the severity of the hearing impairment that might limit its usefulness.¹⁰⁷

A longer questionnaire, the OM7-27, was developed to summarize the outcomes in the MRC TARGET study.¹⁰⁸

The 27 questions cover the seven domains of hearing difficulty, upper respiratory symptoms, sleep patterns, behaviour problems, ENT-related parental quality of life, global physical health and speech/language impairment. It is applicable to children between the ages of three and seven years with OME. The effect of surgery in comparison to nonsurgical management awaits reporting.

Both these questionnaires are potentially useful for research studies, but cannot be described as true quality-of-life instruments. This requires a generic questionnaire that can be used to compare outcomes for different conditions. Many such instruments are available for adults (e.g. the SF-36), but those for children are still in the development stage. A generic Dutch quality-of-life instrument for preschool children (TAPQOL) has been used in a surgical RCT (see Quality of life, under Surgery below) and the communication, positive mood, sleep and aggression domains in this questionnaire relate well to the OME-6 and the Health Utilities Index mark 111.¹⁰⁹

To assess the benefit from interventions, the Glasgow Children's Benefit Inventory has been shown to reflect the parental satisfaction of ventilation tube insertion and allows a comparison to be made between different interventions for different paediatric otolaryngological conditions.¹¹⁰

MANAGEMENT

Counselling and hearing tactics

Parents of children with OME are often misinformed about many aspects of the condition. In particular, they can have overpessimistic views about its severity and be overoptimistic about the merits of surgery. At their first visit to their general practitioner or to a specialist, time has to be spent explaining that, **in general, OME is a benign condition with a high spontaneous recovery rate and no long-term sequelae. In most children, the main concern will be the hearing.** It should be explained to the parents that the impairment associated with OME is very variable in degree and mild or moderate at most.

It is important that all parents of children with OME receive appropriate general counselling about the natural history and relative benign nature of the condition. Those in contact with the child, including any minder or teacher, should be made aware that the **disability can be minimized by hearing tactics, including those shown below:**

- getting the child's attention before starting to talk;
- reducing the background noise as much as possible by turning off the television, etc.;
- facing the child so that they can see you talk;
- speaking in a normal voice both in volume, speed and emphasis, as close as possible to the child;
- leaflets such as *Glue ear explained*¹¹¹ given to the parents can reinforce the above messages.

Medical

Medical management would potentially be of greatest benefit if it could speed the resolution of an episode of OME. Hence, randomized controlled trials carried out in primary care settings would be those most appropriate to consider using resolution of OME as the outcome. Such studies are uncommon and often include heterogeneous groups of children with otitis media rather than OME. The effect of most medications has been systematically reviewed, but the advisability of performing a meta-analysis on the data must be questioned because of the heterogeneity of the studies.

Most trials follow up children for one to two weeks after therapy. If at this point the therapy is ineffective, there is no reason for further follow up as it is unlikely to be of benefit thereafter. However, if it is effective after one to two weeks, then follow up for the recommended watchful waiting period of 12 weeks is necessary to see if it is of benefit in the longer term and might be used to reduce the proportion of children being considered for surgery.

NASAL TOPICAL STEROIDS

Systematic reviews¹¹² [****] of the randomized controlled trials in August 2002 identified one study of topical nasal steroids versus placebo ($n = 44$) that **found no difference in resolution of the OME at three weeks.**¹¹³ [****] Another study which gave antibiotics in addition to nasal steroids also found no difference.¹¹⁴ [****] Both studies randomized small numbers and no subsequent trials have been identified. **It must be concluded that there is insufficient evidence to support the use of topical nasal steroids at present for childhood OME.**

SYSTEMIC STEROIDS

Considerable concern has been expressed about the use of oral steroids being given to children for a nonlife-threatening and spontaneously resolving condition. Consequently, it would have to be highly effective in the long term before it could be recommended. There is no evidence to suggest that oral steroids are effective for longer than in the short term (two weeks) even when combined with antibiotics.^{112, 115, 116, 117} [****] **Systemic steroids cannot be recommended at present for childhood OME.**

ANTIBIOTICS

Multiple randomized controlled trials of antibiotics have been published in heterogeneous groups of patients. Two meta-analyses,^{118, 119} [****] covering the years 1966–1991 and 1993 respectively, reported that **though there might be initial benefit in the first two weeks, there was no evidence of benefit in the longer term (>6 weeks).** Later literature reviews up to 1999¹²⁰ [****] and 2006¹¹⁵ [****]

confirmed that antibiotics had no significant effect on longer-term outcomes. Hence, it is **not recommended** that antibiotics be used for the longer term (>6 weeks) management of childhood OME.

NASAL DECONGESTANTS

A meta-analysis of four trials ($n=1202$) found that antihistamine/decongestants had no significant effect on the resolution rate of OME.^{115, 121} [****] Nasal decongestants are not recommended for use in childhood OME. [Grade B]

MUCOLYTICS

A systematic review of six randomized controlled trials of S-carboxymethylcysteine (Mucodyne) published before 1993 could not demonstrate that they had an effect.¹²² [****] A later trial also showed **no significant effect**.¹²³ [****] Because of a nonsignificant trend for increased benefit in these small, biased trials, a larger well-designed study is merited.

Other approaches

AUTOINFLATION

A systematic review of autoinflation for the treatment of glue ear in children¹²⁴ identified five randomized controlled trials and considered them to be of variable and low quality. Though a metanalysis of the three studies that investigated Otovent balloons indicated that **children allocated to autoinflation were 3.5 times more likely to improve than controls (CI 2.0, 6.1)**, the authors could not **recommend autoinflation for clinical practice**. [****] The ability to autoinflate with the balloon is a particular problem in younger children.

If some form of nonsurgical management is required during a period of watchful waiting, autoinflation is the therapy with the strongest evidence of efficacy for older children.¹¹⁵ [****]

HOMEOPATHY

No randomized controlled trials have been identified. A small, nonblinded **study did not show homeopathy to be of benefit**.¹²⁵ [**]

Surgery

MYRINGOTOMY AND ASPIRATION

From three trials, **myringotomy with aspiration has not been shown to be effective in restoring the hearing levels in children with OME**.¹²⁶ [****]

VENTILATION TUBES

Ventilation tubes can be of different materials (teflon, silicone, titanium, gold, etc.) and be coated with materials such as silver oxide. Their shapes vary but can be categorized as grommets or T-tubes. In general, the larger and stiffer the flange that goes in the middle ear, the longer it stays *in situ*. **The longer a tube stays *in situ* the longer it can be potentially of benefit.** On the other hand, **the longer a tube is *in situ* the greater the chance of complications, including infection, granulation tissue, permanent perforation and thinning of the tympanic membrane with possible retraction.**¹²⁷ [****] The object is then to try and estimate the likely duration of the OME and choose the appropriate tube. Unfortunately, prediction in children of the likely duration of the OME is difficult if not impossible. **However, in adults T-tubes are justified routinely, as in them OME is likely to be persistent over years rather than months.**

Though some classify ventilation tubes as short, medium or long term, data are lacking on 'duration of tube function' as opposed to the more commonly reported and less relevant 'duration till extrusion'. An additional problem is that in studies, follow-up intervals are never less than every three months and often every six months. **In general, the time of extrusion is taken as the midpoint between visits.** This means that duration times are fairly crude estimates. Therefore, most authors prefer to report at set time periods postoperatively. Thus, if one of the most commonly reported tubes is taken, **at six months post-operation 55 percent of Shepard teflon ventilation tubes are functioning**¹⁵ [****] and between 30 and 55 percent are extruded.^{127, 128, 129} [****] **Armstrong tubes have similar extrusion rates, but only 10 percent of T-tubes will have been extruded at six months.**¹²⁷ [****] One potential reason for the range between studies in extrusion times of the same tube is likely to be the varying incidence of recurrent acute otitis media in the children being studied, acute otitis media being more frequent in younger children. Another problem is that even though a tube might have a lower extrusion rate **at 24 months (66 percent for Reuter Bobbin compared with 94 percent for Shepard for example)**, the difference is hardly relevant if 74 percent of the Reuter Bobbins are obstructed.¹²⁷ [****] Thus, at present there is only sufficient evidence to classify ventilation tubes as short or long term.

SURGICAL TECHNIQUE

Site

Insertion of the ventilation tube posterosuperiorly is not recommended because of the potential for damaging the ossicular chain. It makes no difference to the extrusion rate as to whether the tube is inserted through a radial or circumferential incision¹³⁰ and whether sited anterosuperiorly **rather than antero-inferiorly**.^{131, 132, 133} [****] **Placement antero-inferiorly compared with placement**

postero-inferiorly lengthens the time a ventilation tube is *in situ* (for a Shepard tube 80 versus 45 percent at 6 months and 30 versus 15 percent at 12 months are *in situ*).¹³¹ [****]

To maximize the duration of potential tube function, the preferred insertion site is antero-inferior through a circumferential or radial incision. [****]

Associated aspiration

Though it is accepted practice to aspirate as much of the middle ear fluid as possible through the myringotomy before inserting a ventilation tube, there is no evidence that this is required. The hearing levels three months following insertion of a ventilation tube was no different in ears that were aspirated compared with those that were not aspirated.^{134, 135} [****] However, no data are given immediately post-operation when the ears that were aspirated may have had better hearing.

There is no necessity to go to great lengths to remove all middle ear fluid when inserting a ventilation tube. [***]

Topical preparations

These can be used after insertion of the tube to prevent tube blockage with blood and infection in the postoperative period. Their efficacy is discussed under Complications of ventilation tubes.

OUTCOMES OF VENTILATION TUBES

The most up-to-date Cochrane systematic review of 'grommets (ventilation tubes) for hearing loss associated with otitis media with effusion in children'¹³⁶ [****] is based on a systematic literature search to March 2003 with some subsequent papers to August 2004 included. The RCTs of satisfactory quality identified could be divided into those that randomized within a child, one ear to have ventilation tubes and the other ear not to have ventilation tubes ($n=7$) and those where children were randomized to have bilateral ventilation tubes or to watchful waiting ($n=6$). Within the first by-ear category, in three trials all children had adenoidectomy and the other four the children were randomized to have adenoidectomy or no adenoidectomy. In the second category, in five trials none of the children had adenoidectomy and in the other trial children were also randomized to have adenoidectomy or no adenoidectomy.

Time with effusion

In the three studies that provided such data, children who had ventilation tubes without adenoidectomy spent 32 percent (CI 17, 48) less time with effusion during the first year after insertion. After that time most ventilation tubes had become nonfunctioning or had been extruded. In another study¹³⁷ at nine months post-insertion, those that had had ventilation tubes had 46 percent (CI 32, 61) less OME on otoscopy.

Hearing

Ventilation tubes alone will improve the hearing level by 9 dB (CI 4, 14) at six months, 6 dB (CI 3, 9) at 12 months and 4 dB (CI 2, 6) at 24 months. Adenoidectomy has an additional effect of 3–4 dB (CI 2, 5) at six months and 1 dB (CI 0.1, 2.8) at 12 months (Figure 72.17).

A subsequent individual patient data metanalysis of three by-ear trials confirmed that the effect of a ventilation tube in those with an impairment of 25 dB HL or greater when randomized was 10 dB at six months and 3 dB at 12 months.¹⁴¹ [****]

How this magnitude of improvement translates to reduction in hearing disability is not possible to assess in the 'by-ear' studies. Since 1992, the majority of studies have randomized ventilation tubes 'by child' so that hearing disability and other child-centred outcomes can be studied in addition to the hearing levels.

TARGET is a UK multicentre study that looked at the effect of ventilation tubes alone or with adjuvant adenoidectomy on child-centred outcomes. To be eligible, children had to be aged between 3.5 and 7 years and have bilateral OME, persistent over a 12-week 'watchful waiting' period and associated with a hearing impairment in both ears of 20 dB HL or poorer. Children were randomized to one of three arms: no-surgical management, bilateral ventilation tubes (Shepard) or bilateral ventilation tubes with adjuvant adenoidectomy. Figure 72.18 shows the binaural hearing average in the two surgical groups in comparison with the nonsurgical group. The hearing in the nonsurgical group improves with time, mainly due to the natural resolution of the OME. Children randomized to have ventilation tubes had a marked improvement three months following surgery of 12 dB compared with the nonsurgical group.

Figure 72.17 Mean improvement in hearing level and 95 percent confidence intervals after ventilation tube (VT) insertion compared to no surgery (NS). B, Black *et al.*;¹³⁸ D, Dempster *et al.*;¹³⁹ M, Maw and Herod.¹⁴⁰ Redrawn from Ref. 126, with permission.

Figure 72.18 Means and 95 percent confidence intervals of the binaural hearing over the two-year follow up in the ventilation tube (VT), ventilation tube with adenoidectomy (VT + AD) and nonsurgical/medical management (mm) arms of TARGET. Redrawn from Ref. 142, with permission.

It should be noted that in both ventilation tube groups the hearing at three months does not become 'normal'; that is 0 dB HL. If one excludes the small number of ears in which the ventilation tube is nonfunctioning, there is still a material air–bone gap of 13 dB SD 7.¹⁴² [****] At all other postoperative visits, when a tube is functioning, the air–bone gap is of a similar magnitude and, as the middle ear space is well ventilated, is considered due to effusion and oedema around the ossicular chain.

The difference in hearing between the two surgical groups and the nonsurgical group becomes almost negligible at 12 months. The reason for the deterioration in the hearing levels over time in those with a ventilation tube is due to a combination of two factors. The proportion of tubes that become nonfunctioning increases with time, though children were eligible to have them reinserted if the hearing entry criteria were resatisfied. The other reason is that in ears where the ventilation tube has extruded and the OME has resolved, there is still a small but material conduction deficit of approximately 14 dB.¹⁴² [****] The reason why those in the nonsurgical arm improves over that period is mainly due to the natural spontaneous resolution rate of the OME combined with a much smaller contribution from those that switched management arms to surgery.

To summarize from this trial, the improvement in hearing effected by ventilation tubes averaged over the first year was 5.7 dB (CI 3.6, 7.7). In the second year, the difference between the two groups became negligible. Hence, when averaged over two years the benefit of ventilation tubes is reduced to 3.1 dB (CI 1.3, 4.8). These data are not dissimilar to the 'by-ear' studies reported earlier.

A more recent individual data metanalysis of four trials that randomized children to ventilation tubes or watchful waiting confirmed the benefit of short-term ventilation tube at six months, but not at 12 months, with a magnitude of difference of 4.5 dB (CI 2.5, 6.5).¹⁴¹ [****]

It is concluded that short-term ventilation tubes give a benefit to the hearing of 4–5 dB at six months following insertion in those with documented persistent bilateral

OME over a three-month period and a hearing impairment of at least 20 dB HL in both ears. This short-term benefit has to be balanced against the 5–10 dB poorer hearing in late teenage years in ears that have had OME ventilation tubes inserted having controlled for OME severity (see under Long-term hearing impairment above).

Predictive factors for benefit to hearing

To date, no individual study has identified factors that predict which children are likely to benefit most from ventilation tubes. To do this requires a larger study than any performed to date. Alternatively, a metanalysis could attempt to do this, albeit the predictive factors that one might wish to investigate might not have been recorded in all studies. Individual child data have been made available for metanalysis from seven trials that randomized children ($n=1232$) with 12-week persistent bilateral OME to ventilation tubes or nonsurgical management.¹⁴¹ [****] The only factor predictive of a better hearing outcome at six months was attendance at daycare with an impairment of 20/25 dB in both ears. Those without daycare had no benefit (>1 dB) at six months. No effect of age, sex or socioeconomic group was evident. In three trials which randomized children 'by-ear', those with a binaural hearing level of >25 dB HL benefited by 10 dB at six months compared with the 4 dB of those with lesser hearing thresholds.

These data suggest that when the aim is improvement in the hearing, then younger children at daycare and those with binaural hearing thresholds poorer than 25 dB HL and persistent over at least 12 weeks will benefit most.

Hearing disability

In TARGET, the childrens' hearing disability was assessed by a Reported Hearing Difficulty questionnaire. Using standard deviations as a unit of measurement, the difference between ventilation tubes and no surgery over the first year is 'large' even when adjusted for the expectation effect of surgery.¹⁴² [****] Over the two-year time period, the reduction in hearing disability with ventilation tubes was 'modest'.

Speech and language

Three randomized controlled trials have specifically looked at whether ventilation tubes affect speech and language development. The study of Paradise *et al.*¹⁴³ [****] randomized children when they were on average 18 months of age, that of Rovers *et al.*¹⁴⁴ [****] when they were on average 20 months of age and that of Maw *et al.*¹³⁷ [****] when they were 36 months of age. All obtained objective measures of speech and language, including receptive and expressive aspects. All assessed the hearing audiometrically. The design of all three studies was to randomize children to 'early' or 'late' surgery. As with this form of randomization, there is always the potential for those randomized to 'late' surgery to have surgery earlier.

Paradise *et al.*¹⁴³ identified eligible children from a birth cohort of 6350 children. Nine percent were eligible because of the duration of their unilateral or bilateral OME. There was no difference between the early and late surgery groups when followed 18 months after randomization up to when the children were on average three years of age. By then, 34 percent of the early surgery group had had surgery. The children in this trial have now been reported twice subsequently, the last when they were six years of age, which confirmed the lack of benefit of ventilation tubes.¹⁴⁵ [****] The negative outcome of this study may in part be due to the inclusion of children with unilateral OME (63 percent of the sample). Unfortunately, the authors did not report the results of the children with bilateral OME separately.

Rovers *et al.*¹⁴⁴ identified their eligible children from a Dutch birth cohort of 30,099 children. Those who failed a hearing screen at nine months of age three times ($n=1081$) were followed up over four to six months. Those who had persistent bilateral OME ($n=386$; 1 percent of total cohort) were eligible for randomization to 'early' or 'late' surgery. Children were followed up for 12 months at which time, once adjusted for the effects of the mother's education and the child's intelligence, there was no effect of early surgery. In this study, only 9 percent of the late surgery group had early surgery. This study would suggest that children aged 20 months with bilateral persistent OME do not benefit, regarding their speech and language development, from ventilation tubes. This does not mean that children with more severe problems do not benefit; it is just that they have not been studied.

Maw *et al.*¹³⁷ considered children from a birth cohort to be eligible for randomization if they had documented bilateral OME associated with a hearing impairment of more than 25 dB HL persistent over a three-month watchful waiting period. Children also had disruptions to 'speech, language, learning or behaviour', though how this was defined was not stated. The mean age of the children at randomization was three years. At nine months following randomization, those that had not had

surgery were 3.2 months behind in their speech and language, but this difference had disappeared at 18 months. Unfortunately by then 85 percent in the late surgery group had had surgery. Their conclusions were that there is no difference between early and late surgery, but they could not comment upon whether surgery had an effect on speech and language in this age group.

A subsequent metaanalysis of two of these studies¹⁴¹ [****] and a systematic review of all trials^{83, 136} [****] confirmed the null effect of ventilation tubes on children in the first four years of life with OME.

It must be concluded that, in general, ventilation tubes are not indicated to aid speech and language development in children three years and younger.

Randomized controlled trials on severely affected children are merited, but might be difficult to achieve because of their relative rarity.

Behaviour

The UK randomized controlled trial of surgery, described under Speech and language above, of three-year-old children¹³⁷ included serial behaviour questionnaires (Richman) and these were reported in a separate publication.¹⁰⁰ [****] The mean change in the Richman behaviour score nine months following randomization was no different in the children receiving early ventilation tubes as opposed to the watchful waiting group. However at that time, the proportion of children with extremely poor scores was fewer in the surgery group (30 percent compared with 47 percent). The authors chose to highlight the latter finding, but it could be argued that using the mean scores rather than taking an arbitrary cut off is a more relevant and sensitive analysis.

It must be concluded that the effect of bilateral persistent OME associated with a hearing impairment on a child's behaviour is likely to be small and correct spontaneously with time, irrespective of whether they have surgery.

Quality of life

The Dutch study described under Speech and language included a generic quality-of-life questionnaire that covers 13 domains, nine of which would be applicable to children with OME (vitality, appetite, communication, motor problems, social, anxiety, aggression, eating and sleeping). No effect of surgery on this measure of quality of life was identified in the 18-month-old (on average) children with persistent bilateral OME.¹⁴⁴ [****]

Cost-benefit analysis

Such an analysis requires the cost of an intervention to be calculated in terms of a change in a generic quality of life outcome. So, though the cost of surgery was obtained in the Dutch study, as there was no change in the quality of life such an analysis was not relevant.¹⁴⁶ The TARGET study has yet to report a cost-benefit analysis.

COMPLICATIONS OF VENTILATION TUBES

At surgery

The most common immediate complication at the time of surgery is displacement of the ventilation tube into the middle ear (0.5 percent, CI 0.3, 0.7).¹⁴⁷ [****] Efforts should be made to retrieve the tube at the time, but failure to remove it seldom causes problems. Ossicular chain damage will only occur if the myringotomy is placed incorrectly, i.e. posterosuperiorly. Very rarely, a high jugular bulb may be pierced by an inferiorly placed myringotomy.

Immediately post-operation

Blockage of the tube with blood can be prevented to some extent by aspiration at the time of surgery. Syringing has been suggested but is only likely to be effective before the blood dries. [****]

Early infection around the tube occurs in 9 percent of ears (CI 8.5, 9.7).¹⁴⁷ [****] Topical antibiotic steroid drops at the time of surgery can reduce the incidence to 1 percent (CI of difference 3, 12).¹⁴⁸ [****] Some clinicians prolong topical therapy for three to five days after surgery with similar results.¹⁴⁹ [****] The same short-term effect can be achieved with two weeks of prednisolone and trimethoprim,¹⁵⁰ [****] but whether this reduction of infection has any effect on longer-term tube function is doubtful.¹⁵¹ [****]

Otorrhoea

When a ventilation tube is *in situ*, it can be associated with otoscopic evidence of infection with the production of pus that may be clinically evident as otorrhoea. The reason for the infection could be the presence of the tube acting as a foreign body, an episode of acute otitis media with the middle ear pus coming through the ventilation tube, or a combination of both. Making a distinction is difficult, but the younger the child the higher the chances are that the infection is due to an episode of acute otitis media. In addition, the pus can dry and block the tube, increasing the chances of it being extruded.

In a literature review of case-controlled studies and randomized controlled trials of the complications of ventilation tubes inserted in children of all ages and for all indications, approximately 9 percent of parents report

early postoperative otorrhoea (Table 72.15).¹⁴⁷ [***] Thereafter, approximately 7 percent report recurrent acute episodes and 3 percent chronic discharge. However, in children aged between 3.5 and 7 years, where the indication for ventilation tubes is persistent OME, parental report of otorrhoea is of the same magnitude but the otoscopic incidence of infection at any time is <1 percent during the two-year follow-up period (personal communication). [****]

Management of infection is mainly aural toilet with topical antibiotic steroid drops. [*] Secondary granulation tissue occurs in approximately 1 percent of all cases (CI 0.7, 1.3).¹⁴⁷ [***] Granulation tissue is similarly treated with topical preparations. The tube, especially long-term ones, occasionally has to be removed (approximately 4 percent of ears).¹⁴⁷ [***]

Permanent perforation

When a ventilation tube extrudes, an initial pars tensa perforation is inevitable. In the majority, this will heal spontaneously (personal communication). [****] A perforation may then subsequently reoccur at the same site due to a subsequent episode of acute otitis media. Again, in the majority this will heal spontaneously. Thus at any one time following tube extrusion, a proportion of ears will have a perforation which may or may not heal spontaneously. What the proportion is depends on the age of the child and the type of tube inserted. Overall, short-term tubes are associated with a 2 percent incidence of perforations and longer-term tubes an incidence of 17 percent (Table 72.15) an increased relative risk of 3.5 (CI 1.5, 7.1) (Table 72.16).

Once a perforation has been documented as chronic, myringoplasty is the management of choice. This is not usually performed until the child has outgrown having recurrent acute otitis media.

Tympanosclerosis

Hyaline degeneration of the collagen tissue in the fibrous layer of the pars tensa becomes evident otoscopically as localized white patches or plaques of tympanosclerosis. These do not occur in the absence of a history of otitis media. The frequency of tympanosclerosis increases with the frequency of OME (Table 72.12). However, there is a dramatic increased risk difference of 0.33 (CI 21, 45) if a

Table 72.15 Incidence of otorrhoea with indwelling tympanostomy tubes.

Type of otorrhoea	Unit of analysis	Incidence		
		Rate %	95% CI	Range
Early postoperative	Patients	16.0	14.2–17.9	8.8–19.6
Recurrent acute	Patients	7.4	6.0–9.1	0.7–19.6
Chronic	Patients	3.8	2.2–6.0	1.4–9.9
Requiring tube removal	Ears	4.0	3.5–4.5	0–34.3

Table 72.16 Incidence of tympanic membrane sequelae after tympanostomy tube extrusion.

Tympanic membrane sequelae	No of ears	Incidence %	95% CI
Tympanosclerosis	7197	31.7	30.6–32.8
Atrophy or retraction at short-term tube site	1467	25.5	24.2–26.8
Atrophy or retraction at long-term tube site	460	23.3	22.0–24.6
Retraction pocket of pars tensa	543	3.1	1.8–5.0
Chronic perforation, short-term tube	8107	2.2	1.8–2.5
Chronic perforation, long-term tube	3356	16.6	15.3–17.8
Cholesteatoma, short-term tube	8231	0.8	0.6–1.0
Cholesteatoma, long-term tube	1899	1.4	0.9–2.0

Reprinted from Ref. 147, with permission.

ventilation tube has been inserted;¹³⁶ [****] in this instance there being no difference between short- and long-term tubes (Tables 72.15 and 72.16).

In a small proportion of ears, tympanosclerosis is a dynamic process with resolution and occurrence occurring with time.¹⁵² [**] What effect, if any, tympanosclerosis has on the hearing is debated, but has been reported to be up to 3 dB in the short term.¹⁵³ [****] In the longer term at the age of 18 years, there is an impairment of 5–10 dB with a 3–4 dB sensorineural component in those who have had ventilation tubes, having controlled for the OME disease load in childhood.¹⁵⁴ [***] The more tubes that had been inserted, the greater the impairment.

Pars tensa atrophy and retraction

Thinning and retraction of the tympanic membrane is itself considered to be a complication of persistent OME. In children initially referred with bilateral OME, pars tensa retraction to the incus or promontory (Sade grade 3/4) occurs in 8 percent of the better and 10 percent of the poorer hearing ears.^{14, 16, 17} [***] Such retractions were not associated with a history of longer ear problems. Such retractions followed up over a 12-week watchful waiting period resolved in 69 percent of the better and 65 percent of the poorer ears. The OME had also resolved in 14 percent of the better and 10 percent of the poorer ears with a pars tensa retraction, respectively.

Table 72.17 Meta-analysis of tympanostomy tube sequelae.

Outcome assessed	Rate difference (%) (95% CI) ^a	Relative risk (95% CI) ^b
Increase in otorrhoea (long- versus short-term tube)	13.7 (–0.7–28.0)	2.1 (1.0–4.1)
Increase in chronic perforation (long- versus short-term tube)	7.3 (1.3–13.3)	3.5 (1.5–7.1)
Increase in cholesteatoma (long- versus short-term tube)	1.3 (0.4–2.2)	2.6 (1.5–4.4)
Increase in atrophy/retraction (tube versus no surgery or myringotomy)	11.0 (2.6–10.3)	1.7 (1.1–2.7)
Increase in tympanosclerosis (tube versus no surgery or myringotomy)	29.9 (21.9–38.0)	3.5 (2.6–4.9)

^aAbsolute difference in outcomes between groups; $p < 0.05$ when the 95% CI does not include zero.

^bRatio of sequelae incidence between groups; $p < 0.05$ when the 95% CI does not include one.

Reprinted from Ref. 147, with permission.

Pars tensa atrophy also occurs in approximately 3 percent and retraction to the incus or promontory in 2 percent of ears in seven- to eight-year-old children in whom there is no history of OME (Table 72.12). This incidence is similar to that in children with transient episodes of OME. However, the incidence of atrophy, but not of retraction, increases to approximately 9 percent in those with persistent OME. In those who still have a ventilation tube *in situ* for their OME, the incidence of atrophy increases to approximately 68 percent and retraction to approximately 14 percent. It could be argued that this increase in ears with a ventilation tube still *in situ* is because these are more persistent cases, rather than because of the ventilation tube itself. This is in part supported by the fact that the incidence is the same with short- and long-term tubes (Table 72.16 and 72.17).

What can be conclusively inferred is that ventilation tubes do not prevent the occurrence of atrophy or retraction and should not be inserted for that reason alone. [Grade B]

Effect of swimming

A review of the literature in 1993¹⁵⁵ and a Scottish Intercollegiate Guidelines Network review¹²⁰ both come to the conclusion that swimming has no effect on the incidence of reported otorrhoea in children with ventilation tubes. This is supported by the one randomized controlled trial of 212 consecutive children. Of the 50

percent followed up for one year, 68 percent in the swimming compared with 60 percent in the no-swimming group reported otorrhoea. The mean number of episodes was one per year in both groups.¹⁵⁶ [****] It is also unlikely that getting shower or bath water in the ears increases the incidence of otorrhoea. However, there is no substantive literature addressing this question, except laboratory studies that suggest that the pressure would be insufficient for bath water to be forced into the middle ear.

There is therefore no reason to advise against getting water in the ear in children who are fitted with ventilation tubes.

ADENOIDECTOMY

Surgical techniques

Conventionally, adenoidectomy has been performed by blind curettage. This has the advantage of speed, but the disadvantage of relying on the haemorrhage ceasing spontaneously. Temporary nasal packs can be used to encourage haemostasis. Unfortunately, in the immediate postoperative period, bleeding occurs in approximately four percent of children.¹⁵⁷ [**] Suction diathermy ablation, where the tissue is first diathermied then removed by suction, may be associated with less intraoperative blood loss, but haemorrhage in the immediate postoperative period is no less.¹⁵⁷ [**]

Some do not perform the procedure blindly but inspect the adenoids at intervals with a mirror. This has the potential of allowing more selective removal of adenoid tissue and avoiding palatopharyngeal incompetence by leaving an inferior pad of tissue. Microdebriders have also been advocated as allowing more selective removal of tissue. Though visualization is better with this because the tissue and blood are removed by suction, the intraoperative blood loss is no less than by curettage.¹⁵⁸ [***]

Outcomes of adenoidectomy

The mechanism whereby adenoidectomy resolves the OME in some children is unclear, the most popular unproven hypothesis being that it removes a chronic source of infection in the nasopharynx rather than because it removes tissue that physically obstructs the Eustachian tube.

Hearing

Adenoidectomy alone was the conventional surgical management for many years. Since the introduction of ventilation tubes its use has gradually declined because of its lesser overall effect on the persistence of OME and hearing. In the three UK trials, the overall effect at six months on the hearing of adenoidectomy was 8 dB compared with 12 dB for ventilation tubes. Current practice is to perform adenoidectomy as an adjunct to the insertion of ventilation tubes.

Figure 72.19 shows the effect of ventilation tubes along with adenoidectomy in the three UK trials and is presented in a similar manner to the results for ventilation tubes alone (Figure 72.17). The additional benefit of adenoidectomy was approximately 2 dB at 6 and at 12 months. In addition, adenoidectomy reduced the necessity for the reinsertion of short-term ventilation tubes where reinsertion is determined by recurrence of a hearing impairment due to OME (see Revision surgery). Follow up of the children in the Maw and Herod study¹⁴⁰ for a further 12 years¹⁵⁹ [****] showed that the difference of 1–2 dB continues long term. Rather surprisingly, in this study the hearing in all the 12-year-old children who had previous OME was still not normal (approximately 15 dB HL).

The TARGET study confirms the additional benefit of adenoidectomy during the second year of that study (Figure 72.18). Over the first year, the magnitude of the adjuvant effect of adenoidectomy was 2.3 dB (CI 0.6, 4.0) and over two years was 3.3 dB (CI 1.7, 4.8).

Hearing disability

In TARGET, over the two-year follow-up period, the adjuvant benefit of adenoidectomy on the reported hearing difficulty was ‘modest’ (personal communication). [****]

Revision surgery

The proportion of children meriting reinsertion of the ventilation tubes after extrusion because there was still bilateral OME with a material hearing impairment is significantly reduced by adenoidectomy from 47 to 28 percent ($p=0.01$) of children (personal communication). [****]

Detailed data regarding revision after two years of follow up are currently unavailable in any RCT. However,

Figure 72.19 Mean improvement in hearing level and 95 percent confidence intervals after ventilation tube with adenoidectomy (VT + AD) compared to no surgery (NS). B, Black et al.;¹³⁸ D, Dempster et al.;¹³⁹ M, Maw and Herod.¹⁴⁰ Redrawn from Ref. 126, with permission.

hospital activity data suggest that the children who have had an adenoidectomy are less likely to be admitted to hospital and have further surgery for OME extending for a longer period.¹⁶⁰ [***]

Upper respiratory tract symptoms

Adjuvant adenoidectomy improved the reported upper respiratory tract symptoms, as well as the hearing to a 'modest' extent in the TARGET study. The extra benefit is variable and has yet to be shown to be predictable so that adenoidectomy can be offered to children selectively. Interestingly, the mechanism of any benefit is unclear, but it is unlikely to be due to an improvement in Eustachian tube function.¹⁶¹ [****]

Indicators of benefit

Many authors have attempted to analyze which children in their studies are most likely to benefit from adjuvant adenoidectomy. A metanalysis has yet to be reported.

Complications of adenoidectomy

Haemorrhage in the postoperative period is the most feared complication, the incidence depending on how haemorrhage is defined. This can be any blood however small (0.5–8 percent) or the numbers requiring intervention such as blood transfusion or return to theatre (0.5 percent).^{157, 162, 163} [***] Transient velopharyngeal insufficiency can occur in up to 5 percent, but more permanent insufficiency is uncommon (<0.1 percent).¹⁶⁴ [****]

Hearing aids

While hearing aids have been used in children with persistent OME, to avoid repeated surgery their use as the preferred initial management has not been extensively reported. In case series,¹⁶⁵ aids were acceptable to the majority of parents and gave aided thresholds with a mean of 17 dB. [**] The unaided thresholds were not reported, but this improvement is at least in the same range as expected of ventilation tubes. The main concern is potential noise trauma if the aid continues to be worn after the OME has resolved.

BONE-CONDUCTION HEARING AIDS

These have not been considered a viable option until the production of a Softband bone-conduction aid which incorporates a BAHA[®] (bone anchored hearing aid) in a head-band. This method of amplification has the potential advantage over an air-conduction aid in that should the hearing impairment improve during the period of aid issue due to resolution of the OME, then potentially damaging noise trauma would not occur. No report has been identified that has looked at the benefit from the Soft-band aid.

MANAGEMENT OF OME IN CHILDREN WITH CRANIOFACIAL ABNORMALITIES

Children with a cleft palate even subsequent to its surgical repair have a high incidence of OME which in some is a constant condition. As such, how to alleviate their hearing impairment without increasing the risk of developing chronic otitis media has increasingly been achieved with the use of hearing aids rather than ventilation tubes.^{166, 167} [***] The same attitudes apply to the management of OME in children with Down syndrome.¹⁶⁸ [**]

KEY POINTS

- Otitis media with effusion (OME) is the chronic accumulation of mucus within the middle ear and sometimes the mastoid air cell system.
- In children, the prevalence is bimodal with the first and largest peak of ~20 percent at two years of age and a second peak of ~16 percent at around five years of age. [***]
- Natural resolution of the OME is the most likely outcome, albeit there may be further episodes. [***]
- In the majority of children their OME causes only a mild hearing impairment that is unlikely to be disabling. [***]
- Any effect of this hearing impairment on speech and language and cognition is small, of minor significance and likely to spontaneously correct with age. [***]
- The effect of persistent OME on behaviour, though evident, is small. [***]
- Follow-up studies suggest that children who have had OME will still have a small conductive impairment (~10 dB) once the OME has resolved. [***]
- A small conductive impairment is even evident when in their late teens, albeit whether this is a disease effect or the effect of surgery at this age has yet to be clarified. [***]
- Attic retractions are an OME disease effect with an incidence of ~14 percent in the most severely affected children. [***] What proportion of these retractions progress to cholesteatoma is not known.
- There is no evidence that the risk of developing an attic retraction and the potential to develop a cholesteatoma is altered by the insertion of ventilation tubes. [***]
- Tympanosclerosis and atrophy of the pars tensa are OME disease effects, the risk of which is increased by the insertion of ventilation tubes to ~30 and ~25 percent respectively. [***]

- Long-term pars tensa retractions are more likely caused by the insertion of ventilation tubes than by the disease process itself, with an incidence of ~3 percent. [***]
- The benefit of ventilation tubes on children under three years of age with significant language, development or behaviour problems requires investigation.
- In children over the age of three years, the binaural hearing average can be taken as a surrogate of hearing disability, behaviour and impact upon quality of life. In children of this age, OME is unlikely to have a major effect on language or cognition. [***]
- The arbitrary cut-off in hearing thresholds that is taken to indicate a potentially disabling effect that could be improved by ventilation tubes is now taken as 25 dB HL or poorer in both ears. [****]
- All children with hearing thresholds at these levels or poorer should have their hearing documented over at least a 12 week watchful waiting period before any decisions regarding surgery are made. [***]
- Children whose hearing thresholds do not satisfy the hearing criterion of 25 dB HL bilaterally may or may not be followed up 12 weeks later with repeat audiometry.
- Children who persist with OME and a bilateral 25 dB HL over a 12-week-period can benefit from the beneficial effects of ventilation tubes on the hearing over the next nine months. However, the effect is small and is maximal at three months of a magnitude of 12 dB. [****]
- Even when a ventilation tube is functioning, there is still a residual conductive impairment of around 13 dB. [****]
- This relatively small benefit to the hearing has to be balanced against the longer term deleterious effects of ventilation tubes on the tympanic membrane which are associated with poorer hearing. This balance of benefit against harm has to be fully discussed with and appreciated by the parents or carers.
- There is no evidence that a pars tensa retraction in association with OME is an indicator of chronicity or greater benefit from ventilation tubes. [***]
- If ventilation tubes are to be inserted there is a strong argument that adenoidectomy should be performed at the same time, particularly if there is concern regarding the general health of the upper respiratory tract. [***]
- Adenoidectomy extends the period of benefit to the hearing of short-term ventilation tubes up to two years by a magnitude of around 2 to 3 dB. [****] It also reduces the proportion

of children eligible for reinsertion of short-term tubes from around 50 to 25 percent. [****]

- No predictors of benefit from adenoidectomy have been identified. Whether adjuvant adenoidectomy is merited for this small gain in hearing, given the risk of postoperative bleeding in 4 percent of children, is unresolved.

Best clinical practice

In primary care

- ✓ OME should be suspected in children who have recently recovered from an episode of acute otitis media and in those presenting because of parental concern regarding their hearing. [Grade B]
- ✓ Attention should be paid to parental concern regarding their child's hearing, particularly if there is a history of recurrent acute otitis media. [Grade B]
- ✓ All children should have otoscopy to confirm OME and exclude AOM or COM. [Grade C]
- ✓ Unless specifically trained in otoscopy, this is likely to be insufficiently sensitive or specific even if performed with a pneumatic otoscope to reliably make the diagnosis of OME. [Grade B] Tympanometry should perhaps be more available in primary care.
- ✓ In primary care the unreliability of otoscopy and non-availability of tympanometry should not cause concern as it is the disability of a bilateral hearing impairment persistent for longer than 12 weeks that is the indicator for referral for audiometric assessment, rather than suspicion of OME.
- ✓ Free-field voice testing is therefore a more meaningful assessment to perform. [Grade B]
- ✓ No medical therapy has been shown to be effective longer term (more than six weeks) including antibiotics [Grade A], topical nasal steroids, systemic steroids, nasal decongestants and mucolytics. [Grade B]
- ✓ In the older child, auto-inflation with the help of 'Otovent' balloons may be beneficial. [Grade B]
- ✓ It is important that all parents of children with OME receive appropriate general counselling about the natural history and relative benign nature of the condition. [Grade D] This includes advice regarding hearing tactics (see above under Counselling and hearing tactics).
- ✓ If there is persistent concern regarding the hearing in any child, then referral for hearing assessment is indicated. This will detect previously unsuspected sensorineural impairments as well as quantify any hearing impairment associated with OME. [Grade D]

- ✓ In most cases, such referral should be for hearing assessment and a further period of audiometric monitoring, rather than for consideration of ventilation tubes. [Grade B]

In secondary care

- ✓ Pure-tone air-conduction thresholds should be assessed in all children referred with suspected OME and a hearing impairment at their first visit. Not masked bone-conduction thresholds should be obtainable in the majority of 3.5 years or older children. This will aid management of those with OME and detect the ~1 percent with previously undiagnosed sensorineural hearing impairments. [Grade B]
- ✓ Otoscopy and parental reports of hearing are insufficient to predict current hearing thresholds. [Grade B]
- ✓ Otoscopy, supplemented by tympanometry if there is any doubt as to whether there is OME, should be performed in all children. This, along with the hearing thresholds, should enable the children with OME to be categorized as having unilateral or bilateral disease, and if bilateral whether the impairment in both ears is ≥ 25 dB HL. This distinction is relevant to future management in secondary care. [Grade B]
- ✓ Thereafter, all parents of children with OME should receive appropriate general counselling about the natural history and relative benign nature of OME. [Grade D]
- ✓ The hearing levels associated with the child's OME should be discussed with the parents and advice about hearing tactics given to help the parents mitigate any disability (see above under Counselling and hearing tactics). [Grade D]
- ✓ There is insufficient evidence to support the use of topical nasal steroids at present for childhood OME. [Grade B]
- ✓ Systemic steroids cannot be recommended at present for childhood OME. [Grade B]
- ✓ It is not recommended that antibiotics be used for the longer term (more than six weeks) in the management of childhood OME. [Grade A]
- ✓ If some form of nonsurgical management is required, auto-inflation is the therapy with the strongest evidence of efficacy for older children. [Grade B]
- ✓ As there is no evidence that medical therapy is beneficial, clinicians in secondary care have the task of identifying those that might benefit from surgery after a period of watchful waiting.
- ✓ Children with unilateral OME are unlikely to develop bilateral OME. [***] In general, children with unilateral OME do not merit follow-up at secondary care and should not have ventilation tubes inserted. [Grade A]
- ✓ Myringotomy with aspiration has not been shown to be effective in restoring the hearing levels in children with OME and is not recommended without the insertion of ventilation tubes. [Grade A]

- ✓ In children under the age of three years, ventilation tubes are not indicated even in cases with persistent bilateral OME if there are no language, development or behaviour problems. [Grade A] They therefore do not merit routine follow-up at secondary care.
- ✓ In general, ventilation tubes are not indicated to aid speech and language development in children aged three years and younger. [Grade A]
- ✓ The effect of bilateral persistent OME associated with a hearing impairment on a child's behaviour is likely to be small and correct spontaneously with time. Correspondingly, a child's behaviour is not an indication for surgery. [Grade B]
- ✓ Ventilation tubes do not prevent the occurrence of atrophy or retraction and should not be inserted for that reason alone. [Grade B]
- ✓ Short-term ventilation tubes are of proven benefit to the hearing up to nine months following insertion in children with bilateral OME documented to have been persistent for at least 12 weeks. The magnitude of the effect is around 4 to 5 dB. It is recommended that such ventilation tubes be limited to those most likely to benefit; children with a hearing impairment of at least 25 dB HL in both ears audiometrically documented to have persisted for at least three months. [Grade A]
- ✓ To maximize the duration of potential tube function, the preferred insertion site is antero-inferior through a circumferential or radial incision. [Grade A]
- ✓ In arriving at a decision regarding surgery, the deleterious effects of ventilation tubes in the longer term on tympanic membrane scarring (RR 0.33), thinning and poorer hearing (5 to 10 dB) must be discussed with the parents to enable any consent to be fully informed. [Grade D]
- ✓ There is no reason to give advice against getting water in the ears in children who have ventilation tubes. [Grade D]

Deficiencies in current knowledge and areas for future research

- Otitis media with effusion and acute otitis media in children is the most researched area in otology.
- As such, a high proportion of the important clinical questions on otitis media with effusion have already been satisfactorily addressed for the mild to moderately affected child.
- What requires investigation are children with the extremes of persistence of OME, such as occurs in children with craniofacial abnormalities.
- The ideal therapy would be a preventative one, such as immunization to reduce the frequency of upper respiratory viral and bacterial infections.

- For those who develop OME, medical therapy which manages the mucosal aspects of the condition are more likely to be beneficial than surgical therapy.
- It is important to have confirmation by better controlled studies of the more serious otological damage, such as retraction that occurs to the tympanic membrane following ventilation tube insertion.
- How to best change the attitudes to ventilation tubes of surgeons and parents given their paucity of benefit for any length of time and their permanent damaging effect is perhaps the aspect most requiring research in OME.

SEARCH STRATEGY

The data in this chapter are supported by searches of Medline and the Cochrane Controlled Trials Register, using the term acute otitis media. Reference lists were reviewed for further articles, and authors of recent presentations contacted personally for their reference lists.

INTRODUCTION

For such a common childhood infection, acute otitis media (AOM) remains something of an enigma. It is hard to diagnose accurately and on existing evidence, as opposed to custom and tradition, there is still a high level of uncertainty over how it should best be treated. This is against a background of increasing bacterial resistance to antibiotics. There is plenty of evidence in the literature of the relative frequencies of viral and bacterial pathogens in AOM, but this is often of little help to the clinician on the spot in an individual case. Some of the epidemiological evidence is also relatively 'soft', since it is based on the flawed premise that AOM can accurately be diagnosed from the history and otoscopy alone, unsupported by tympanometry or tympanocentesis. In this chapter, the authors have tried to thread their way through the often conflicting evidence about the practical management of AOM at the same time as covering what is known of the pathology, epidemiology and complications of this commonest of childhood illnesses.

We have found ourselves uncomfortably often using expressions such as 'uncertainty,' 'insufficient evidence,' or 'limited information,' and quoting [****] and [***] levels of evidence. Even a metanalysis, the supposed gold standard of evidence, is only as good as the studies it covers. It must be remembered that the prevalence of otitis media with effusion (OME), 'glue ear,' only began to be widely appreciated after the development of the twin tools of universal hearing screening and the tympanometer in the 1960s and early 1970s, respectively. The accuracy of correct reporting of cases of AOM lags behind that of OME mainly because in the majority of large population studies of AOM the essential presence of fluid in the middle ear is not confirmed by tympanometry and audiometry.

DEFINITION

AOM may be defined clinicopathologically as inflammation of the middle ear cleft of rapid onset and infective

origin, associated with a middle ear effusion and a varied collection of clinical symptoms and signs. It is synonymous with acute suppurative otitis media. It normally develops behind an intact tympanic membrane, but may include acute infections arising in the presence of ventilation tubes or existing tympanic membrane perforations. The requirement to confirm a middle ear effusion, and the nature of the symptoms and signs, vary between authors.^{1,2}

The literature supports four broadly defined subgroups of AOM.

1. **Sporadic episodes** occurring as infrequent isolated events, typically occurring with upper respiratory tract infections.
2. **Resistant AOM:** persistence of symptoms and signs of middle ear infection beyond three to five days of antibiotic treatment.
3. **Persistent AOM:** persistence or recurrence of symptoms and signs of AOM within six days of finishing a course of antibiotics.
4. **Recurrent AOM:** either three or more episodes of AOM occurring within a six-month period, or at least four or six episodes within a 12 month period (no consensus has been reached on the latter).

Groups two and three appear similar at first glance and this distinction may be questioned. It is included to maintain some consistency with the wider literature.

Grading of the severity of an episode has been attempted and has merit both clinically and for research. Pyrexia from 37.5–39°C, vomiting and severity of otalgia have been used.^{3,4} [*]

DIAGNOSIS

Diagnosis is based on the combination of often nonspecific symptoms, evidence of inflammation of the middle ear cleft and, by some authors, by the additional confirmation of a middle ear effusion. Diagnostic difficulty has affected the quality of research into AOM. There may well not be a clear history of a crescendo of otalgia in a coryzal child, followed by rapid symptomatic relief associated with tympanic membrane perforation and associated blood-stained otorrhoea. The difficulty in establishing clear diagnostic guidelines has been highlighted in an analysis of 80 studies of AOM.⁵ In diagnosing AOM, only 52.5 percent of the studies cited middle ear effusions, 32.5 percent included symptoms and signs of inflammation and 2.5 percent considered the rapidity of onset. Clinicians recognize this difficulty. A large multinational study rated clinicians diagnostic certainty in children under one year of age at only 58 percent, rising to 73 percent in those over 31 months.⁶

Symptoms

Diagnosis by symptomatology alone is inaccurate because of the young age of most patients, and the nonspecific nature of the symptoms. One-third of children may have no ear-related symptoms. Two-thirds may be apyrexial.⁷ Symptoms suggestive of AOM include rapid onset of otalgia, hearing loss, otorrhoea, fever, excessive crying, irritability, coryzal symptoms, vomiting, poor feeding, ear-pulling and clumsiness (Table 73.1). AOM most commonly develops three to four days after the onset of coryzal symptoms. The otalgia will settle within 24 hours in two-thirds of children without treatment.⁹ The otorrhoea, if present, is mucopurulent and may be blood-stained. Symptomatic relief is obtained without treatment in 88 percent by day four to seven. The hearing loss, caused by the middle-ear effusion, occurs early in the illness and may persist at greater than 20 dB for one month in over 30 percent, and two months in 20 percent of children. [**/*]

Signs

The child may appear unwell, and may rub his or her ear. The diagnosis is often confirmed, rightly or wrongly, by an attempt at otoscopic assessment of the tympanic membrane. However, a poorly functioning otoscope, the moving target of a child's head, the narrow ear canal of an infant, the natural redness of the tympanic membrane of a screaming child, wax and, above all, the inaccuracy of an untrained (or even trained) eye, straining to interpret a two-dimensional image, all combine to make otoscopy an imprecise art. Since trained observers have been shown to have only an 85 percent accuracy in otoscopic diagnosis,¹⁰ it would not be surprising for a sensible primary care physician to rely more on history and the general aspect of a child than on otoscopic findings. With these reservations, diagnosis may be supported by otoscopic assessment of tympanic membrane colour, position and mobility (Figure 73.1). In AOM the tympanic membrane is usually opaque. It is most commonly yellow, or

Table 73.1 Relation of reported symptoms to presence of AOM in 302 children under four years of age.

Symptom	Sensitivity	Specificity	Positive predictive value	Negative predictive value
Earache	60	92	83	78
Restlessness	64	51	46	68
Rhinitis	96	8	41	74
Cough	83	17	40	61
Fever	69	23	38	53

Figure 73.1 Otoscopic findings in early AOM.

yellowish pink in colour, being red in only 18–19 percent.^{7,10} The position of the tympanic membrane reliably predicts AOM only when it is bulging. Hypomobility of the drum demonstrated by pneumatic otoscopy has been shown to aid diagnosis¹⁰ and is felt essential in some countries,¹ although others including the Dutch² take a more pragmatic view and do not include this in their diagnostic criteria. Should the drum have perforated, or a ventilation tube be *in situ*, mucopurulent otorrhoea will be seen. [**/*]

Investigations

Tympanometry may be used to establish the presence of a middle ear effusion, but is not usually available. Tympanocentesis and culture of middle ear effusion have been used in a number of studies assessing diagnostic accuracy of clinical signs, and establishing the organisms prevalent in a community. It is rarely required to make the diagnosis, though may be considered in high risk children such as the immunocompromised, an unwell neonate, those that fail to respond to conventional treatment and children who are seriously ill or have complications of AOM. Taking a bacterial swab of persistent otorrhoea following perforation is recommended. Nasopharyngeal swabbing for bacterial culture has been assessed but the correlation with middle ear organisms has been too weak to recommend it clinically.¹¹

Specific investigation may be prompted by recurrent AOM not responsive to conventional treatment. Both iron deficiency anaemia and white blood cell disorders have been associated with AOM, so a full blood count is indicated. Immunoglobulin assay may be appropriate: Ig A, G (with subclasses) and M are typically assessed. Children

with recurrent infection of ventilation tubes may also merit investigation for primary ciliary dyskinesia, particularly if nasal and pulmonary symptoms coexist. [**/*]

Differential diagnosis

Pain may be referred from tonsillitis, teething, temporomandibular joint disorders or simply be the result of an uncomplicated upper respiratory tract infection. In a screaming child, the tympanic membrane may well appear red. Diagnostic confusion may occur with acute mastoiditis, otitis media with effusion, otitis externa, trauma, Ramsey Hunt syndrome and bullous myringitis. Very rarely, AOM may be the first indication of serious underlying disease, such as Wegener's granulomatosis or leukaemia.

AETIOLOGY

Microbiological, anatomical and environmental factors combine with altered host defence mechanisms to predispose to infection. Genetic predisposition to recurrent AOM is being increasingly cited in the literature.

Infective agents

AOM results from infection of the middle ear cleft. Both bacterial and viral infections are implicated. These infections may occur in isolation or combination.

VIRUSES

Clinically it is apparent that AOM is commonly associated with viral upper respiratory tract infections. As our ability to identify these improves, the role of viruses in the aetiology of AOM is becoming clearer. Increasing use of polymerase chain reaction assays for respiratory viruses suggests 60–90 percent of cases of AOM may be associated with viral infection.¹² In one study, a specific viral cause of upper respiratory tract infection was shown in 41 percent of children with AOM.¹³ The viruses most commonly associated with AOM vary between studies, but in decreasing frequency include:

- respiratory syncytial virus (RSV);
- influenza A virus;
- parainfluenza viruses;
- human rhinovirus;
- adenoviruses.

This heterogeneity is important when considering vaccination against viruses as a prophylactic measure.

The mechanism by which they give rise to AOM is likely to vary between viruses. Viral material has been demonstrated in the middle ear aspirates of children with

AOM in 48–71 percent of cases.¹² The viral material may arrive either passively along the Eustachian tube along with other nasopharyngeal secretions or may actively invade the middle ear cleft possibly by haematogenous spread. These alternative routes of entry are suggested by the wide variation in rates of isolation of specific viral strains in the middle ear during systemic infection, ranging from 4 to 74 percent of cases dependent upon the specific virus. If all arrived passively, similar rates of isolation would be expected. This implies some viruses may be actively invading the middle ear cleft, and may be contributing directly to mucosal inflammation. RSV invaded the middle ear most frequently.¹³ In contrast, those arriving passively appear to cause AOM by virtue of their action on the Eustachian tube, on bacterial adherence, and on host immunity.

There is good clinical and animal evidence that viral infection affects Eustachian tube function.¹² At a cellular level there is release of multiple inflammatory mediators from cells within the nasopharynx. Ciliated epithelial cells numbers decline, mucus production increases in the Eustachian tube and negative middle ear pressure results. This is likely to predispose to AOM.

Alteration of host immunity has been documented after viral infections, increasing susceptibility to bacterial infections. Cell-mediated immunity has been shown to be affected by RSV infection, and neutrophil function altered by influenza viruses. In a study of children with bronchiolitis caused by RSV, 62 percent developed AOM. Bacteria were isolated from the middle ear in all these children.

The ability of bacteria to colonize and adhere to the nasopharyngeal epithelium appears to be increased by certain viral infections. Increased colonization by pathogenic bacteria may predispose to AOM.

Viral and bacterial infection coexist in the middle ear cleft in AOM in as many as two-thirds of cases where viruses have been identified. This is important as clinical studies show that children who have both viruses and bacteria in their middle ear are very much more likely to have a poor response to antibiotics when compared to those with bacteria only (33 versus 3 percent failure respectively, in one study¹⁴). Why this should be is unclear, but may be related to the greater concentrations of inflammatory mediators in ears in which both bacteria and viruses are present. [**/*]

BACTERIA

The bacteria isolated from the middle ear in AOM are shown in Table 73.2.^{15, 16}

In persistent or recurrent bacterial AOM, repeat culture of middle ear aspirates has failed to grow pathogenic bacteria in 30–50 percent of patients, implying that inflammation may persist despite the eradication of the infecting organism. The spectrum of organisms is similar to that in isolated episodes. In the 1980s *H. influenzae* was the most common organism identified

Table 73.2 Bacteria associated with AOM.

Bacteria	Incidence (%)
<i>Haemophilus influenzae</i>	16–37 ^a
<i>Moraxella catarrhalis</i>	11–23
<i>Streptococcus pyogenes</i>	Up to 13
<i>Staphylococcus aureus</i>	Up to 5

^aThere are some 90 serotypes.

in persistent or recurrent AOM, but this has been replaced by drug-resistant *Pneumococcus*. After antibiotic treatment for recurrent AOM it is now estimated that 50 percent of *H. influenzae* are beta-lactamase producing. A similar proportion of pneumococci are penicillin resistant.¹⁶ Penicillin resistance in pneumococci results from decreased penicillin binding protein on the bacterial cell walls, so reducing the affinity for penicillin-related drugs, but means that resistance may often be overcome by increasing drug dosage. This is not the case with beta-lactamase producing organisms. Most *Moraxella catarrhalis* are now beta-lactamase producing.

Studies on HIV-positive children suggest a similar spectrum and prevalence of infecting organisms as occurs in immunocompetent children, except where the child is severely immunosuppressed, when a higher percentage of *Staphylococcus aureus* has been reported. [**]

Routes of spread of infection

Three potential routes are described: the Eustachian tube, tympanic membrane perforations or grommets, and haematogenous.

The Eustachian tube is traditionally assumed to be the main route by which organisms reach the middle ear, though there are relatively few studies to confirm this. It is speculated that negative middle ear pressure may facilitate the movement of bacteria up the Eustachian tube.¹⁷ Circumstantial evidence is also gained from similarities in organisms cultured from the post-nasal space and the middle ear cleft in AOM. Whether anatomical or physiological differences predispose to AOM is unclear. Studies of Native Americans, who are prone to otitis media, suggest their Eustachian tubes are shorter, straighter and more patulous than in whites, but also that they have a low passive tubal resistance.¹⁸ Research has found no difference in tubal dimensions in otitis prone and non-prone children. However, altered tubal function may play a role. Specifically, otitis-prone children have been shown to have significantly poorer active tubal function (muscular opening function).

Pathogen entry through tympanic membrane perforations or ventilation tubes is most commonly associated with water exposure.

Haematogenous spread is inferred from the evidence provided by studies of viral identification in the blood and middle ear as described previously. It was shown that the wide variation in rates of identification of specific viral strains from the middle ear could not be explained by passive Eustachian tube transport alone.¹² [**/*]

Risk factors

GENETIC FACTORS

There is growing evidence that recurrent AOM is largely genetically determined. It is likely many genes are involved. There are numerous studies suggesting a familial association. A metanalysis of risk factors has shown that when one family member had AOM the risk increased for other family members (relative risk 2.63).¹⁹ Racial differences are well described with increases in American Indians, Eskimos and Australian Aborigines. However, environmental factors, such as poor economic status, may contribute to the increased risks in these groups. The most powerful evidence comes from twin studies, in particular comparison of monozygotic and dizygotic twins in whom the occurrence of AOM was compared.¹⁸ Many immune related mechanisms, which are likely to have a genetic basis, have been proposed. Certain human leukocyte antigen (HLA) classes have been shown to be significantly associated with increased risk of AOM. Maternal blood group A is reported to an independent risk factor (relative risk 2.82). Atopy has also been associated with increased risk of developing AOM. [****/***/*]

IMMUNE FACTORS

Our understanding of the immune response to AOM remains incomplete. However, a number of specific associations have been identified which suggest that certain defective or immature pathways may predispose to infection. Low levels of IgG2 subclasses have been reported in several studies to be more common in otitis-prone children. Those with IgG2 deficiency were shown to be three times more likely to develop post-ventilation tube insertion otorrhoea for example. Delayed maturation of anti-pneumococcal antibodies (IgG1 and IgG2 were studied) does appear to predispose to AOM. This may explain in part why children grow out of AOM as immunity matures.

Defective complement-dependent opsonization has been associated with recurrent AOM and diarrhoea in infancy.¹⁸ This is caused in some examples by low concentrations of mannose-binding protein which acts as an opsonin. This appears to be a common defect with over 20 percent of children with recurrent AOM affected in some studies. This may be particularly important in infancy when the antibody repertoire is limited.

Aberrant expression of critical cytokines, such as tumour necrosis factor and interleukins, resulting in suboptimal host defence, has been postulated as a cause for persistent infection. Expression of mucin genes, at least nine of which have been identified, may differ in those predisposed to AOM. Middle ear mucosa expresses specifically the MUC5B gene. Mucin genes regulate the production of mucin. Limited evidence is beginning to emerge that over-expression may alter the mucociliary transport system.¹⁸

A number of studies on children with HIV infection have yielded conflicting results. Advanced disease associated with low CD4 counts does seem to be associated with an increased incidence of AOM. [**/*]

ENVIRONMENTAL FACTORS

There are many reports on the relative contribution of environmental factors. These are important as it may be possible to modify them. The most important is almost invariably stated to be day-care attendance outside the home. The larger the number of children in the group, the greater the risk. Day care outside the home carries a relative risk (rr) for AOM of 2.45, compared to a risk of 1.59 for children cared for in their own home. The incidence of AOM appears to follow that of seasonal upper respiratory tract infections (URTI) in the winter months. Breastfeeding for three months is protective (rr, 0.87). Use of a pacifier (dummy) carries a relative risk of 1.45.¹⁹ Poor socioeconomic status associated with poor housing and overcrowding has been reported to be associated with AOM (overcrowding: rr, 5.55 in a Greenlandic population, for example). Passive smoke exposure from parental smoking is weakly associated (rr, 1.0–1.6). There is more limited evidence to support the role of dietary factors, in particular cow's milk allergy, in predisposing to AOM. [****]

SYNDROMIC ASSOCIATIONS

Syndromes associated with abnormalities of skull base anatomy are well recognized as being associated with chronic middle ear disease, but less is published on associations with AOM. Children with Turner's syndrome do suffer more frequent episodes of AOM. Down syndrome predisposes to middle ear disease, including AOM. In cleft palate there is only a minor increase reported. Certainly Eustachian tube dysfunction in these groups predisposes to middle ear effusion, but it is not clear whether it is this dysfunction or an increase in risk secondary to subtle immunological factors that predisposed to infection. No increase is found in children with primary ciliary dyskinesia if grommets are not inserted, or cystic fibrosis.

A direct association between iron deficiency anaemia, and the degree of anaemia and frequency of AOM has been reported. [**]

EPIDEMIOLOGY

AOM is one of the commonest illnesses of childhood. It accounts for approximately 25 percent of all prescriptions for children under ten years of age in the USA, for example. Its incidence appears highest in the first year of life, more specifically the second six months of life in most studies, and gradually reduces with increasing age. This progression was shown by Strangerup and Tos²⁰ who reported an incidence of a first episode of AOM in 22 percent in the first year of life, 15 percent in year two and 10 percent in year three, falling to 2 percent by year eight (Figure 73.2). Epidemiological studies have been compromised by difficulty in achieving accuracy in diagnosis when large numbers of children are being assessed, hence there are wide variations in reported numbers. Incidences of over 60 percent are stated in some reports of infants up to age one year. By age three years, some 50–70 percent of all children will have had at least one episode of AOM, and at least 75 percent by the age of nine years.

The incidence of AOM certainly varies with the seasonal incidence of viral upper respiratory infections. There are reports that it is increasing over a period of years. Possible reasons include increased day nursery attendance and changes in diagnostic awareness.

Recurrent AOM has been reported in 5 percent of children under two years of age. Others have reported that by age three, half of children will have had at least three episodes. An important indicator of future problems is a first episode before nine months of age: these children have a one in four risk of developing recurrent AOM.

In the first two years of life, AOM occurs bilaterally in 80 percent of cases. After six years of age, it is unilateral in 86 percent.²⁰

MANAGEMENT OPTIONS

Most children with AOM will get better quickly and without treatment. Some will not. A very small number

Figure 73.2 Cumulative incidence of acute otitis media (i.e. how many children have had at least one episode in their life). Redrawn from Ref. 20, with permission.

may develop potentially serious complications. Current debate questions whether and for whom treatment is required, and the role of prophylactic strategies. As serious complications are rare it can be difficult to obtain high quality evidence of how effective are prophylaxis and the treatment of episodes of AOM in preventing such complications.

Management of acute episodes

CONSERVATIVE TREATMENT

Most children will benefit from simple analgesics and anti-pyrexials, in a quiet supportive environment. Paracetamol and ibuprofen are most commonly used in the UK. There is limited experimental animal evidence showing that ibuprofen provides additional benefit by reducing mucosal inflammation when taken in combination with amoxicillin.

MEDICAL TREATMENT

Antibiotics

Uncertainty over the use of antibiotics is reflected in wide variations in usage between countries, ranging from 31 percent in the Netherlands to 98 percent in the USA.⁹ There is, however, an increasingly good evidence-base for the most appropriate management in children over two years of age. In children under two, the evidence-base is weaker.

Antibiotics, if not prescribed initially, should be given to a child who fails to improve after two to three days of 'watchful waiting', and to all children with an 'irregular' illness course. They should also be given to 'high risk' children, defined by the Dutch as children with craniofacial abnormalities, Down syndrome, immunodeficiencies and those under the age of two years suffering a recurrent episode of AOM.² Guidelines must be adapted to suit local experience, for example in regions of the world with a high incidence of complications of AOM where all patients may be regarded as high risk.

A recent metanalysis⁹ has addressed the question of whether antibiotics should be given at initial consultation. Two-thirds of children recovered within 24 hours of the start of treatment, and 80 percent by days two to seven, with or without antibiotics. This, of course, raises the question as to whether the children did indeed have AOM in the first place. Antibiotics did lead to 5 percent fewer children overall having pain between days two and seven. That equates to 17 children needing to be treated to prevent one child experiencing pain during days two to seven. Relatively few data were available on hearing loss at one and two months post-infection, but no differences were found between those who received antibiotics and those who did not. No significant differences were found

on progression of disease or relapse of symptoms. Similarly, no differences were found in complications of AOM. However, those taking antibiotics suffer nearly double the side effects, such as diarrhoea, than those who do not, and run a greater risk of developing antibiotic resistant bacteria.

The length of treatment was addressed in a separate metaanalysis.²¹ Short (five day) and long (ten day) courses of treatment were compared. At 8–19 days the weighted mean failure rate in the short course was 19 percent and 13.7 percent in the long course. By days 20–30, this had converged to 15.7 versus 12.5 percent, which was nonsignificant. It implied that 17 children would need to receive the long course to avoid one treatment failure. The authors concluded that five days of treatment was appropriate in uncomplicated infections in low risk children over two years of age without recurrent AOM or tympanic membrane perforation. Under two years of age evidence is weaker that short course treatment is adequate.

Attempts have been made to identify a subgroup of children who may benefit from antibiotics. Younger age may be an important determinant, but good evidence is lacking because of diagnostic difficulties in this group. However, while published data show only modest benefit from antibiotic treatment between six and 24 months of age²² (number needed to treat (NNT)=seven for one symptomatic improvement at day four), most would recommend treatment below two years of age. Using short-term symptomatic outcome markers at day three, it has been shown that immediate antibiotics may benefit those children presenting with higher temperatures ($>37.5^{\circ}\text{C}$) or vomiting (NNT = 3–6).⁴

AOM occurring in the presence of a tympanic membrane perforation or ventilation tubes may be treated equally successfully with oral or topical antibiotics. The potential ototoxicity of topical aminoglycoside ear drops in these cases is well recognized and dose dependent, therefore prolonged topical treatment should be avoided. [****]

Which antibiotic?

This should be determined by national recommendations. Amoxicillin remains the first choice in most centres, but at higher than previously recommended doses (80 mg/kg/day) if drug-resistant pneumococci are common in a particular country or region, or macrolides for penicillin-sensitive patients. For persistent or resistant episodes, national policies should be sought depending on the prevalence of beta-lactamase-producing organisms and culture results if available. Options include amoxicillin-clavulonate or cefuroxime axetil orally, or intra-muscular ceftriaxone (US Centre for Disease Control and Prevention).

Antihistamines and decongestants

A metaanalysis of the use of oral or intranasal antihistamines and/or decongestants concluded that their use could

not be supported, and that medication side effects were higher when they were used together. While combining the two treatments was shown to slightly reduce persistent AOM at two weeks (NNT=10.5) the result may have been biased by the design of the studies.²³ [****]

SURGICAL TREATMENT

Surgery has a limited role in the treatment of an uncomplicated episode of AOM. Myringotomy was practised in the pre-antibiotic era, and indeed was continued until the late 1980s in some countries as a first-line treatment for AOM. However, there are now a number of good studies showing that myringotomy plus antibiotics offers no advantage over antibiotics alone. Myringotomy alone has a worse outcome than either of the antibiotic groups.²⁴ Myringotomy is reserved for severe cases where complication is present or suspected, to relieve severe pain or when microbiology is strongly required. [****]

Management of recurrent acute otitis media

ALTERATION OF RISK FACTORS

It may be possible to alter many of the environmental risk factors discussed previously. Parents should be reassured of the benign natural history of AOM, as these children have been shown to be more demanding than those without recurrent disease, and their mothers more anxious about their care. The most readily modifiable risk factor is exposure to other children. AOM increases with the number of children in day care, the length of time a child spends in day care each week, how young a child is when introduced into day care, the presence of children under two years of age in the day-care setting and having a sibling in day care. Advice should include sitting a child semi-upright if bottle-fed and avoiding passive smoke inhalation. Restricting the use of pacifiers, particularly after infancy, should be recommended for otitis-prone children. The mother may be advised to continue breastfeeding for at least six months after future pregnancies and increasing vitamin C intake and avoiding alcohol in the third trimester, both of which have been weakly associated with AOM. The role of food allergies, in particular cow's milk, is still unclear. No effective role has as yet been shown for homeopathic remedies. [**]

MEDICAL PROPHYLAXIS

Antibiotics

Antibiotic prophylaxis has the potential to cause problems, but should be considered for recurrent AOM. Many organisms need to be covered so a broad-spectrum drug is required. Risks for the development of resistant

organisms increase, adverse drug reactions may occur and active disease may be masked. Studies of prophylaxis of recurrent AOM invariably treat each individual recurrence with additional antibiotics. Trials therefore compare antibiotic prophylaxis versus placebo between acute episodes. The natural history of recurrent AOM is reassuring. Over 50 percent of children having no treatment between attacks will not suffer a further episode in the following six months. Indeed, only one in eight continues to suffer recurrent AOM (i.e. three or more episodes) during the trials, if treated only for acute episodes. However, metanalysis does show a benefit of antibiotic prophylaxis equating to a reduction of approximately 1.5 episodes per 12 months of antibiotic treatment given, above that expected from the natural history. So one child would need eight months of treatment to avoid one episode of AOM. There was a trend for those treated with sulfisoxazole to do better than those treated with amoxicillin, both being used at half the therapeutic dosage.²⁵ Recommendations are for six months of treatment through the winter months in children who do not have background OME.

Those studies that assessed the length of time a child has OME in association with AOM showed that while antibiotic prophylaxis may reduce the incidence of AOM, it does not reduce the length of time with OME. This is important as antibiotic prophylaxis may therefore be most appropriate for children not prone to OME, while ventilation tubes may be indicated for those prone to OME.

Most trials exclude 'high risk' children, who are often most in need of treatment. On the basis of the metanalysis described above, which shows a modest benefit with the use of antibiotic prophylaxis, there may also be a place for its use in the management of high-risk children with recurrent AOM, despite the absence of specifically targeted studies. [****]

Xylitol

Xylitol is a commonly used sweetener that inhibits pneumococcal growth and the attachment of pneumococci and *Haemophilus* to nasopharyngeal cells. Studies in daycare nurseries using chewing gum or syrup have suggested reductions of 30–40 percent in the occurrence of AOM. However, this translates to 1–1.5 episodes per year.²⁶ It is ineffective if used in acute upper respiratory infections. Given the very large quantities that must be consumed, and potential concerns over the safety of such consumption, its use cannot yet be recommended. [***]

Vaccination

Vaccines have been used effectively against most common childhood infections caused by single specific organisms such as mumps, measles and rubella. The concept of vaccinating against AOM therefore is an attractive one that is being actively explored. Potential obstacles include the wide range of causative organisms, both bacterial and viral, the varied serotypes, technical difficulties in

producing an effective immune response, obtaining an immune response before six months of age, parental resistance to multiple vaccination and the possibility that the successfully targeted pathogens will simply be replaced by others.

Vaccination against viruses

Since 60–90 percent of episodes are initially associated with viral infections (see above under Viruses) viral vaccination seems the most logical first step. AOM secondary to infection by the measles virus is now relatively uncommon in industrialized countries, for example.

Influenza A vaccination is currently the only commercially available preparation for the prophylaxis of viral upper respiratory infections. Three trials of children in daycare have shown its efficacy in preventing AOM, resulting in 30–36 percent fewer episodes during a subsequent influenza epidemic, and reducing influenza-associated AOM by 83–93 percent.²⁷ This is not an absolute reduction in episodes, and this indication is not yet within the UK Department of Health guidelines.²⁸ This does show, however, that preventing viral URTI can be an effective method of reducing AOM. [***]

RSV vaccines are undergoing clinical trials for lower respiratory tract infection, but as yet do not seem to be providing significant protection. No studies are under way assessing a role in AOM.

Parainfluenza virus vaccines have been evaluated in animals and need to target types 1, 2 and 3 viruses. Limited human studies demonstrate relative safety and immunogenicity, but efficacy studies are not available.²⁹

Vaccination against bacteria

Vaccination against *Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae* and *Moraxella catarrhalis* is made difficult by the low immunogenicity of the polysaccharide capsule of these bacteria in young children and infants. Success against *Haemophilus influenzae* type B (which causes epiglottitis and meningitis) using a polysaccharide-protein conjugated vaccine provides one potential solution.

Streptococcus pneumoniae vaccination is particularly challenging because of the 90 serotypes of the bacteria. However, as only a small number of these cause most pneumococcal AOM, and it has been shown that anti-capsular antibodies can prevent pneumococcal AOM, progress has been made. Early attempts with unconjugated pneumococcal polysaccharide vaccines proved unsuccessful in children under two years of age. However, a heptavalent conjugated vaccine (Prevenar, Wyeth-Lederle Vaccines) has been shown to be highly effective in preventing invasive pneumococcal disease and modestly successful in reducing AOM in two major studies. Immunization occurs at two, four, six and 12, and in one study also 15 months of age. Episodes of AOM from any cause were reduced by 6 and 7 percent, respectively, and pneumococcal AOM by 34 percent.²⁹ To improve cover

during the critical first six months of life, trials are under way to see if immunizing the mother in the third trimester of pregnancy is effective. Immunization after two years of age is with 23-valent pneumococcal polysaccharide vaccine. Whilst vaccination is recommended in certain 'at risk' children,²⁸ its place in the management of AOM is not yet clear. It may be, for example, that vaccinating a child presenting with recurrent AOM will be ineffective because colonization of the upper respiratory tract has already occurred. Publications on this are pending. Debate on the quality of systematic reviews on this topic continues and clear guidance cannot yet be given.³⁰ [***]

Non-typeable *Haemophilus influenzae* vaccines are being developed by several techniques.²⁷ Phase I clinical trials using a conjugated vaccine are under way. Animal experiments using a chinchilla model have shown some reduction in AOM with this type of vaccine.

Moraxella catarrhalis vaccine research is at a preclinical stage, but products are under development.

Experts in the field hope vaccination against all three of these bacteria may be possible within a decade.²⁹

Special attention should be drawn to children with, or awaiting, cochlear implants. Concern has been raised about a number of cases of meningitis. Whether it is implant related or reflects inner ear abnormalities in many of these children is unclear. All such children are recommended to have the heptavalent pneumococcal vaccine before the age of two years and the 23-valent pneumococcal polysaccharide vaccine at the age of two or over (see Chapter 70, Paediatric cochlear implantation). Hib conjugate vaccine is recommended for all children up to four years of age.

Immunoglobulins

The importance of immunological immaturity in the occurrence of recurrent AOM has been emphasized. Intramuscular pooled gamma-globulin in otitis-prone children has been shown not to reduce the incidence of AOM. However, in a Japanese study, intravenous immunoglobulin (GB-0998) in IgG2-deficient infants has been shown to be an effective prophylaxis for AOM, as well as pneumonia in this specific group of children. [**]

Benign commensals

A recent paper considered whether spraying benign commensals (alpha streptococci) into the nose to recolonize the nasopharynx following antibiotics might reduce AOM by inhibiting the growth of pathogenic bacteria. A significant reduction was reported.³¹ A separate smaller study, which did not pretreat with antibiotics, showed no difference. [***]

SURGICAL PROPHYLAXIS

In contrast to the large number of trials comparing antibiotic treatments, there are relatively few addressing

surgical prophylaxis. Surgery is potentially attractive, however, in that it may reduce problems of antibiotic resistance and also treat subsequent OME.

Ventilation tubes

A recent metanalysis of five trials concluded that the presence of ventilation tubes versus no tubes yielded a relative decrease in episodes of AOM of 56 percent, equivalent to an absolute reduction of 1.0 episode per child per year.³² The effect occurred mostly in the first year of follow up, presumably as this covered the period when the tubes were in place. Of equal importance is the reduction in the prevalence of OME by 115 days per child-year. Seventy-nine percent were reported to have an improved quality of life. Side effects included recurrent otorrhoea in 7 percent and chronic otorrhoea in 4 percent. Other studies have shown a higher incidence of tympanosclerosis and focal areas of tympanic membrane atrophy of questionable significance in the ventilation tube groups.

These findings need careful interpretation. One of the studies compares antibiotic prophylaxis with amoxicillin to tubes to placebo.³³ The amoxicillin group had a significant reduction in episodes of AOM. The tube and placebo group did not. However, when AOM occurred in the placebo group, it was more distressing than when otorrhoea occurred with AOM in the group with tubes in place. Also, over a two-year period, the surgical group had 26 and 61 days fewer with OME than the antibiotic and placebo groups, respectively.

It is difficult to draw conclusions about the role of ventilation tubes. On the evidence available they may be considered for children with recurrent AOM, but no persistent effusion, in whom medical strategies have failed. There may be a greater role for them in preference to, or following failure of, medical prophylaxis in the child with recurrent AOM and persistent OME. [****]

Adenoidectomy and adenotonsillectomy

The limited evidence-base for best practice is most striking when considering adenoidectomy. Two papers are particularly worth discussing, both with a cohort of children from Pittsburgh. Randomization methods have been questioned in these studies, as has follow up. The first concluded that adenoidectomy may be beneficial in children who had previously had ventilation tube insertion and suffered subsequent AOM. AOM was reduced by 31 percent relative to the control group in a two-year follow up (or 0.32 episodes per child-year), and subjects spent 42 percent less time with OME. Additionally, the need for further tubes was reduced by 50 percent.³⁴

Their second trial was of children who had not previously had ventilation tube insertion. Considering children without overt adenotonsillar disease, a modest reduction in the number of episodes of AOM was recorded in the first year after surgery from 2.1 to 1.4

following adenotonsillectomy, but not adenoidectomy. Similarly, OME was reduced from 30 to 19 days in year one in the adenotonsillectomy group, and to 22 days in the adenoidectomy group. The effect was not apparent after the first year. Drop out from the trial was particularly high in the adenoidectomy group, and the results should be viewed cautiously. For children with adenotonsillar symptoms, no AOM benefit was reported from adenotonsillectomy. The authors concluded the risks of surgery were not warranted in children who had not previously had ventilation tube insertion.

In summary, there is little evidence to support adenotonsillectomy. Adenoidectomy may be considered in those children who have failed medical therapy and had further AOM following ventilation tube insertion. The presence of OME increases the benefit of adenoidectomy. [***]

OUTCOMES

An episode of acute otitis media may resolve rapidly with or without antibiotics; it may prove resistant to first-line antibiotics; it may persist or recur shortly after a course of antibiotics has finished; it may subsequently recur; or it may progress to tympanic membrane perforation or other complication of infection. Here we consider the medium- and long-term consequences of infection: the natural history of AOM, middle ear effusions, auditory functioning and speech and language development.

Natural history

Data come from the control arms of randomized controlled trials, and hence usually exclude high-risk children, complicated cases, and those under two years old. Without antibiotic treatment, symptomatic relief from pain and fever occurs in approximately 60 percent of children within 24 hours of diagnosis, in over 80 percent by day two to three, and 88 percent by days four to seven.^{9, 25} These data do not equate with complete resolution, for example otorrhoea may still be present without pain or fever, and only 73 percent reach the stage of complete resolution by day seven to fourteen. In all studies, those with resistant or persistent disease will have received antibiotic treatment.

For recurrent AOM the prognosis is also generally favourable. Following study entry, and with only acute episodes treated, recurrence rates fell to 0.13 episodes per child per month in the subsequent 6–24 months – approximately 1.6 episodes per year. Indeed, over half had no further attack in the following six months, and only one in eight continued to satisfy the diagnostic criteria for recurrent AOM.²⁵ Other work has shown that even in early recurrences of infection three to four weeks after a previous episode, a new organism is usually involved.

Caution should be attached to these findings. Though pooled numbers are large, high risk children and those with baseline OME were generally excluded.

MIDDLE EAR EFFUSIONS

Middle ear effusions are an important outcome of AOM. Looking again at those children randomized to placebo, pooled data show rates of OME of 63 percent two weeks after AOM, 40 percent at one month and 26 percent at three months. Antibiotics did not appear to have any effect.^{9, 25}

AUDITORY FUNCTIONING

What little work has been carried out on short-term audiometric outcomes suggests that approximately one in three children will have an air–bone gap greater than 20 dB at one month after infection, and one in five at three months. There is limited evidence to suggest that AOM may reduce long-term audiometric thresholds. Several studies following cohorts of children have reported small but significant loss of very high frequency hearing (11–16 kHz) in those with many episodes of AOM. There is a suggestion that this may be more a consequence of disturbed middle ear mechanics than cochlear damage. The significance for auditory functioning as the child grows older is not established.

SPEECH AND LANGUAGE DEVELOPMENT

It is difficult to separate the literature on AOM and OME outcomes. Little is written on speech production or reception. In children with OME, a significant effect seems to occur in the early years of life on expressive language development, but not receptive language. A small number of studies point to persisting effects on expressive language in school-age children. There is little evidence showing different cognitive development in school-age children with a history of otitis media in the first three years of life. There are suggestions that poor behavioural traits may be more common by school age, but more work is required before conclusions are drawn.

COMPLICATIONS

Extracranial

TYMPANIC MEMBRANE

Tympanic membrane perforation is considered a complication of AOM. It is the commonest complication of infection and is reported in 0–10 percent of episodes. Perforation is associated with a purulent or bloody otorrhoea and immediate relief of pain. It typically occurs

in the posterior half of the pars tensa, and is associated with loss of the fibrous middle layer of the drum. This may predispose to future posterior retraction pockets. Four outcomes of perforation may result. In most cases the perforation heals spontaneously and the infection resolves. Second, the infection may resolve, but the perforation persists. This may predispose the ear to future AOM or chronic suppurative otitis media. Third, the perforation and otorrhoea may persist, manifesting as chronic suppurative otitis media. 'Chronicity' is generally deemed to have occurred by three months. Fourth, a further complication may arise.

The long-term outcomes were assessed in a cohort of otitis-prone children followed up from 3 to 14 years of age. By the end of the study 7 percent had collapse of the posterior superior tympanic membrane, chronic suppurative otitis media, or central perforation.³⁵ Scarring or tympanosclerosis was present in 27 percent, although several studies report that ventilation tubes increase this risk.

ACUTE MASTOIDITIS

1. mucosal

Four classes of mastoiditis are defined. During episodes of acute otitis media, infection and inflammation may naturally extend into the mastoid cavity, and be visualized radiologically. This is not associated with the typical signs of acute mastoiditis and is not considered a complication of AOM.

2 Infection may spread to the mastoid periosteum by emissary veins: acute mastoiditis with periosteitis. At this stage no abscess is present but the post-auricular crease may be full, the pinna may be pushed forward and there may be mild swelling, erythema and tenderness of the post-aural region.

3 When acute mastoid osteitis develops, the infection has begun to destroy the bone of the mastoid air cells and a subperiosteal abscess may develop. Signs may be similar to those when periosteitis is present. A subperiosteal abscess develops most commonly in the post-auricular region. A zygomatic abscess may develop above and in front of the pinna. A Bezold's abscess may result from perforation of the medial mastoid cortex, tracking down the sternomastoid to the posterior triangle. Pus tracking down peritubal cells may result in a retropharyngeal or parapharyngeal abscess (Figure 73.3).

A fourth stage may be reached, subacute ('masked') mastoiditis, in incompletely treated AOM after 10–14 days of infection. Signs may be absent, but otalgia and fever persist. This stage can also progress to serious complications.³

In the pre-antibiotic era, mastoiditis was a common and serious complication of AOM. In a study in 1954 the control group was reported to have developed mastoiditis in 17 percent of cases.⁹ In some developing countries rates of 5 percent are still quoted. In the 1970s it was estimated that 0.004 percent of cases of AOM resulted in surgery for

Figure 73.3 (a) and (b) Acute mastoiditis.

mastoiditis. The incidence is reported by several authors to be increasing gradually again. The incidence varies between countries. In the UK, Canada, Australia and the United States, where antibiotic prescription rates are over 96 percent, the incidence ranges from 1.2 to 2.0 per 100,000 population per year. In Norway, Denmark and The Netherlands (prescription rates 67, 76 and 31 percent, respectively) rates are higher at 3.5, 4.2 and 3.8 respectively.³⁶

Acute mastoiditis is a disease of childhood. A large multicentre study found 28 percent to be in children less than one year of age, 38 percent in one to four year olds, 21 percent in four to eight year olds, 8 percent in 8–18 year olds and 4 percent in those over 18 years of age.³⁷ This higher incidence in younger children reflects the peak ages for AOM.

Traditional teaching was that acute mastoiditis is preceded by 10–14 days of middle ear symptoms. However, in many papers the short length of middle ear symptoms prior to presentation is noteworthy. For example, in one large study approximately 32 percent had one to two days symptoms, 34 percent had three to six days, 26 percent seven to fourteen days and 8 percent over 14 days.³⁷ Prior antibiotic treatment of the infection is common, reported in 22–55 percent of children. Clearly antibiotics do not fully protect against mastoiditis.

Symptoms are of otalgia and irritability in most children. Pyrexia is less common in those treated with antibiotics. Otorrhoea is present in only approximately 30 percent. Clinically, a red or bulging tympanic membrane will often be seen. A normal drum is reported in a very variable proportion of cases, but certainly does not exclude the diagnosis and is believed to result from resolution of the mesotympanic infection following antibiotic treatment, while the osteitis in the mastoid progresses. Retro-auricular swelling is seen in approximately 80 percent and retro-auricular erythema in 50–84 percent (less in previously treated children). Tenderness is typically sited over MacEwen's triangle (on palpation

through the conchal bowl). Pinna protrusion is present in two-thirds of cases. Sagging of the posterior wall of the external auditory canal, resulting from subperiosteal abscess formation, should be looked for, but is quoted as an uncommon finding. Few patients will have a 'full house' of the classic signs.

A somewhat different incidence of organisms has been identified from those gained from culture in AOM. Around 20 percent of samples do not grow bacteria. *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Pseudomonas aeruginosa* and *Staphylococcus aureus* are the most commonly reported. *Haemophilus influenzae* is less commonly reported, and *Moraxella catarrhalis*, *Proteus mirabilis* and Gram-negative anaerobes rarely.

Recommended investigations vary between institutions. A full blood count, C-reactive protein (CRP), and blood cultures are often obtained. A CT scan of the mastoid is recommended when intracranial complications are present or suspected (though MRI may be more helpful in identifying specific intracranial pathology), when mastoidectomy is to be performed and in those not improving on antibiotic treatment. A CT may show evidence of osteitis, abscesses and intracranial complications.

Differential diagnosis includes AOM, otitis externa, furunculosis and reactive lymphadenopathy. Rarely, undiagnosed cholesteatoma, Wegener's granulomatosis, leukaemia and histiocytosis may first present with AOM, hence tissue should be sent for histology if mastoidectomy is performed.

Myringotomy with or without ventilation tube placement, culture of the aspirate and high-dose intravenous antibiotics is the most commonly recommended initial treatment in acute mastoiditis. This is adequate in 75 percent of cases. Failure to improve, subperiosteal abscess formation (occurring in 10–30 percent) or development of complications merits at least abscess drainage with or without cortical mastoidectomy. This can be challenging surgery for the less experienced as the mastoid is often full of granulations and the facial nerve superficial in the young child.

A most important message is that intracranial complications from acute mastoiditis develop in 6–17 percent of cases, and many of these may develop during hospitalization. Although acute mastoiditis may be less common than in the past, its severe complications still occur. [*]

PETROSITIS

Infection may extend to the petrous apex. The classic features of Gradenigo's triad (VI nerve palsy, severe pain in the trigeminal nerve distribution and middle ear infection) are not always present. Patients commonly present with other intracranial complications. Recent papers recommend high-dose broad spectrum antibiotics and a variety of mastoidectomy, from cortical to radical, though drainage of the petrous apex is no longer felt necessary. [*]

FACIAL NERVE PALSY

In the pre-antibiotic era, it was estimated that acute lower motor neurone facial palsy complicated 0.5 percent of episodes of AOM (see Chapter 80, Facial paralysis in childhood). It is now quoted at 0.005 percent.³⁸ Most are related to bacterial infection but case reports with viral AOM exist. Approximately four out of five children present with a partial paralysis. The case series in the literature report that approximately 80 percent of palsies respond well to ventilation tube insertion and intravenous antibiotics. The remainder undergo cortical mastoidectomy. Advice is conflicting about when and in whom mastoidectomy is required and the role of facial nerve decompression. As recovery is generally so good, a more conservative approach without facial nerve decompression seems appropriate. Most children achieve rapid restoration of normal facial function, with a mean time to complete recovery of four months. Those with a total paralysis at presentation have a recovery stretching over many months.

Sixth nerve palsy in the absence of petrositis has also been reported. It is speculated this may stem from phlebitis spreading along the inferior petrosal sinus from the lateral sinus. [*]

LABYRINTHITIS

Round window permeability changes during acute infection are important as these may allow entry of bacterial toxins. There is some experimental evidence that permeability can be increased by streptococcal toxins. Preformed channels for bacterial entry may also exist, such as surgical or congenital perilymph fistulae. These may allow infection to spread directly to the subarachnoid space causing meningitis. Particular concern arises in children with congenital inner ear abnormalities and those with cochlear implants. Three types of labyrinthitis are recognized. *Perilabyrinthitis* is not associated with AOM. *Serous labyrinthitis* is inflammation of the labyrinth without pus formation, and is characterized by recovery of auditory and vestibular function. *Suppurative labyrinthitis* may result from spread of infection from the mastoid or middle ear. Severe vertigo, nausea, vomiting, nystagmus and permanent hearing loss result. Suppurative labyrinthitis is rare, and the treatment of cases presented in the literature ranges from ventilation tube insertion and aggressive antibiotic use, to tympanomastoidectomy and cochleotomy. [*]

Intracranial

In the pre-antibiotic era, intracranial complications of AOM were more common and mortality rates of over 75 percent are presented. Published mortality rates from intracranial complications now average approximately 5 percent in industrialized countries.

Persistent headache and fever are the most common early symptoms of an intracranial complication. In half of cases there may be signs only of AOM and not mastoiditis. Frequently two or more complications coexist. Early diagnosis is important for improving outcomes.

Seven classical intracranial suppurative complications of AOM are described.³

1. **Meningitis** is usually cited as the commonest intracranial complication of AOM, accounting for 54–91 percent of cases. In contrast, studies assessing the aetiology of meningitis are conflicting. One of the largest recent studies found no association between bacterial meningitis and AOM, while another found an antecedent history of AOM in 29 percent,³⁹ though this does not equate to a causal relationship. Special mention has already been made of possible associations between congenital inner ear malformations such as cochlear dysplasia, cochlear implants and meningitis. Younger children, average age two years, are most commonly infected. Studies focus almost exclusively on bacterial aetiologies. The rate of *Haemophilus influenzae* type B meningitis has dropped dramatically since vaccination was introduced. *Streptococcus pneumoniae* is the causal agent in a greater proportion because of this reduction.³⁹ A second intracranial complication should be looked for in any infant with meningitis with MR scanning. Myringotomy may help to establish the infective agent if evidence has not been obtained from lumbar puncture. Treatment is medical. If mastoid surgery is required, it is usual to try and wait for an improvement in the medical condition of the child first if possible. [*]
2. **Extradural abscess** is the next commonest intracranial complication. It is more commonly associated with chronic disease. Pus collects between dura and bone, usually after bone erosion. If lying in the posterior fossa medial to the sigmoid sinus, it is termed an extradural (epidural) abscess, if within the split of dura enclosing the sigmoid sinus it is called a peri-sinus abscess. It may be discovered only at mastoidectomy, but may be suspected in the patient with persistent headache and fever or severe otalgia. Treatment is surgical drainage. [*]
3. **Subdural empyema** is a collection of pus between the dura and arachnoid membranes and is termed a subdural empyema. It is rare. It develops by direct extension of infection or thrombophlebitis. In addition to headaches and pyrexia, focal neurological signs, seizures and signs of meningeal irritation may be present. Paranasal

sinusitis is reported to be a much commoner cause than AOM. Surgical drainage of the abscess through burr holes or craniectomy may be indicated. Mastoidectomy may sometimes be required, though many cases cited in the literature were treated medically. [*]

4. **Sigmoid sinus thrombosis** most commonly results from erosion of the bone over the sinus from mastoiditis and may also be associated with other complications. However, it occurs in association with otitis media alone in 43 percent of cases. Infected thrombus develops within the sinus and may then extend proximally and distally to the internal jugular vein and superior vena cava, entering the systemic circulation and causing septicaemia. In addition to headache and otorrhoea, a spiking pyrexia may develop. Griesinger's sign is mastoid tenderness and oedema secondary to thrombophlebitis of the mastoid emissary vein. MRI is the imaging of choice showing high signal intensity in the sigmoid sinus on both T₁- and T₂-weighted images and absent flow. If caused only by otitis media, myringotomy and antibiotics may suffice. However, in the presence of mastoid infection, it is more usual to perform a canal wall up mastoidectomy, needle the sinus to assess blood flow and occasionally to remove infected thrombus. As persistent sepsis and distant thrombosis are uncommon, the role of anticoagulation is unclear in the literature.⁴⁰ Serial imaging to look for propagation of thrombus has been recommended. [**/*]
5. **Focal otitic encephalitis (cerebritis)**. Focal inflammation and oedema of brain tissue may occur independent of, or in association with, any suppurative complication of AOM. Intensive antibiotic treatment is required. [*]
6. **Brain abscess** is more commonly associated with chronic ear disease but may occur in association with AOM and its complications (Figure 73.4). Brain abscess forms a larger proportion of complications in developing countries. It may develop in both the temporal lobe and cerebellum. Persistent headaches are the commonest symptom. Initial symptoms may be of encephalitis, but these often settle as the abscess organizes over days or weeks. Eventually, signs of raised intracranial pressure, focal neurology and infection develop. Investigations include CT imaging followed by lumbar puncture, if safe. In the early stages of cerebritis, neurosurgical drainage may be avoided but will be required if the abscesses are expanding. Brain abscesses carry a potentially high mortality rate, although in industrialized countries the few large

© Hodder Arnold / Scott-Brown 7E

Figure 73.4 Brain abscess secondary to AOM.

series now quote rates of below 10 percent. One large review found the mortality from otogenic causes, at 3.8 percent, was much lower than from other causes. [*].

7. **Otitic hydrocephalus** is a complication of AOM manifesting as raised intracranial pressure in the absence of any space-occupying lesion, and without obstruction to the flow of cerebrospinal fluid (CSF). Benign intracranial hypertension is a synonym. The aetiology is obscure. Headache is the predominant symptom. It is commonly associated with sigmoid or transverse sinus thrombosis and so MRI is an important investigation. Lumbar puncture will show raised CSF pressure, but normal CSF composition. A number of medical treatments may be tried and liaison with a paediatric neurologist is recommended. [*].

CONCLUSION

It can be seen from this chapter that there are deficiencies in our current knowledge of both the diagnosis and aetiology of AOM, and uncertainties in management strategies. However, we have been able to describe a number of potentially exciting developments that have occurred in the past few years.

KEY POINTS

- Acute otitis media is one of the commonest illnesses of childhood.
- Diagnosis can be difficult particularly in very young children.
- Management recommendations vary widely between countries.
- A range of modifiable risk factors should be addressed.
- Evidence is emerging to support new prophylactic strategies.
- Intracranial complications are still seen despite prior antibiotic treatment.

Best clinical practice

- ✓ AOM is one of the commonest illnesses of childhood. Accurate diagnosis is notoriously difficult. A high index of suspicion is required in the unwell child. [Grade B]
- ✓ The clinician should distinguish between sporadic, resistant, persistent or recurrent AOM as management strategies differ. [Grade A]
- ✓ Two-thirds of children recover within 24 hours with or without treatment, so a period of watchful waiting may be reasonable in uncomplicated AOM. [Grade A]
- ✓ Antibiotics should not be withheld in severe or irregular infections, should be given if a child fails to improve within two to three days of the onset of AOM and should be given in sufficiently high doses. [Grade A]
- ✓ Pyrexia ($>37.5^{\circ}\text{C}$), severe otalgia, vomiting, age under two years and 'high risk' children have all been used as indicators to use antibiotics sooner rather than later. [Grade B/C]
- ✓ Practitioners should be aware of local bacterial antibiotic resistance patterns and prescribing policies. Broad spectrum antibiotics are not generally required as first-line therapy. [Grade A]
- ✓ In otherwise healthy children over two years of age, five days of antibiotics is usually adequate. [Grade A]
- ✓ For persistent or resistant AOMs it should be noted that whilst pneumococcal drug resistance can usually be overcome by increased antibiotic doses, *Haemophilus* may be beta-lactam producing, so broader spectrum antibiotics may be required. [Grade B]
- ✓ Modifiable risk factors should be discussed with parents. These include nursery attendance, parental smoking, breastfeeding and the use of pacifiers. [Grade C]

- ✓ In the management of recurrent AOM, on average eight months of antibiotic prophylaxis would be needed to prevent one episode of AOM. This strategy may be preferred in the absence of effusions between episodes of AOM. [Grade A]
- ✓ Ventilation tube insertion reduces the number of episodes of AOM by over 50 percent. This option may be preferred when effusions persist between episodes of AOM. [Grade A]
- ✓ Additional adenoidectomy may further reduce the number of episodes of AOM. [Grade A]
- ✓ The benefits of tonsillectomy on episodes of AOM are not sufficient to warrant its use in the management of recurrent AOM. [Grade A]
- ✓ Vigilance should be maintained for complications of AOM, the most common symptoms being persistent pyrexia and headache. [Grade C].

Deficiencies in current knowledge and areas for future research

The following list summarizes what we feel this chapter should be able to report on when the next edition is being prepared.

- Greater standardization and reproducibility of diagnostic criteria is required to compare trials.
- As most children appear to recover without treatment, better characterization of those who may have initial antibiotic treatment withheld is needed.
- Trials should be set up to study high risk groups of children who are currently excluded from most studies: those with conditions predisposing them to acute otitis media and children under 18 months of age. These are the children likely to benefit the most from our intervention.
- We know many important risk factors, but trials are needed to show whether attempts to modify them actually help.
- The potential benefit of vaccination to older children with recurrent infection needs exploring. As more vaccines are developed, we must know to whom we should be recommending them.
- The number and quality of trials of surgical intervention does not allow confident guidance to be given as to the long-term benefits or consequences of ventilation tube insertion.
- More data are required on the long-term consequences of recurrent infection in terms of altered audiometric thresholds, quality of life and language and cognitive development.

ACKNOWLEDGEMENTS

We would like to thank Dr Anne Schilder from the University Medical Center, Utrecht, for her data on management practices in the Netherlands.

SEARCH STRATEGY

The data in this chapter are supported by Medline searches through the PubMed online database using medical subject headings (*inter alia* otitis media; otitis media, suppurative; tympanic membrane perforation; tympanoplasty; myringoplasty; cholesteatoma, ossicular prosthesis, etc.). Searches were curtailed by using the 'child (0–18)' limiter and by focusing on appropriate subheadings in the medical subject headings database. Free text searches using terms not included in the medical subject headings database such as 'tympanic membrane atrophy' and 'tympanic membrane retraction' were expanded and refined using Boolean operators. Results were stored using reference manager software (Endnote), which also allowed searches to be combined without duplication of results. The Cochrane database was also consulted. These electronic searches were extended by reference to proceedings of major international symposia, particularly the series of international otitis media conferences, the international cholesteatoma meetings and the middle ear mechanics series.

INTRODUCTION AND DEFINITIONS

In any specialized field new terminology is introduced to facilitate dialogue between interested parties. These specialized terms require precise definition in order that communication and comparison between centres can have any value at all. However, in any developing area of human endeavour a rudimentary subject may be found to harbour several new aspects of interest. This development not only leads to the introduction of new terms in the field of study but also the reclassification of the parent subject. In this way, the progressive change caused by increasing understanding of a subject paradoxically may

complicate its teaching. The following problems may arise.

- Older classifications and definitions may become obsolete.
- Some terms may become repeatedly defined and therefore ambiguous.
- Increasing complexity of classifications, whilst of value to those developing the subject, may hinder their widespread use. The balance between precision and utility may have no perfect solution.

The study of chronic otitis media has resulted in all these problems.

WHO definition of chronic otitis media, 1996

A WHO/CIBA Foundation Workshop¹ in 1996 produced the following definitions:

- **Chronic suppurative otitis media:** 'a stage of ear disease in which there is chronic infection of the middle ear cleft, i.e. Eustachian tube, middle ear and mastoid, and in which a non-intact tympanic membrane (e.g. perforation or tympanostomy tube) and discharge (otorrhoea) are present'. The same report qualifies this definition by stating that the otorrhoea should be present for two weeks or longer.
- **Chronic otitis media:** 'includes both chronic suppurative otitis media and chronic perforation of the tympanic membrane'.

International Symposium on Recent Advances in Otitis Media, 1978

A task force was appointed on behalf of this symposium² to provide definitions of terms relevant to otitis media, as well as a classification of the subject. It proposed *inter alia*:

- **chronic otitis media:** 'a chronic discharge from the middle ear through a perforation of the tympanic membrane'.
- **chronic otitis media** and **chronic suppurative otitis media** were defined as synonymous.

However, the definitions continued that 'suppurative refers to active clinical infection'. Furthermore, 'a perforation without discharge can be an inactive stage of the infection'.

As the term 'chronic suppurative otitis media' appears here to be considered equal to 'active chronic otitis media' there is not only some inconsistency within this set of definitions but a clear path for this evolution of these terms. As a result, the terms 'active chronic otitis media' and 'inactive chronic otitis media' have also enjoyed widespread use.

The unambiguous part of the original definition was the perforation. Unfortunately, this elevated the presence of a perforation as sufficient to establish the existence of chronic otitis media. Given that tympanic membrane perforations need not be caused by chronic otitis media, this was manifestly wrong. This is particularly true in the paediatric population in which a common cause for tympanic membrane perforation is acute otitis media. In most such cases, the perforation heals with resolution of the acute infection without a phase of chronic infection.

International Symposium on Recent Advances in Otitis Media, 1999

A panel reporting to the Post-Symposium Research Conference of this Symposium has issued a revised classification of otitis media.³ The panel produced an

exhaustive and hierarchical classification of otitis media (see **Table 74.1**). Nonetheless, the new classification continues to have difficulty with 'chronic otitis media', not only denying the term its significance as an immediate subclassification of otitis media but also refuting the validity of the term. The panel report states that: 'the term chronic otitis media is confusing and potentially misleading and should not be used, since some consider it to mean chronic otitis media with effusion, others think it means chronic suppurative otitis media, and still others include cholesteatoma under this term'.

The panel prefers the term 'chronic suppurative otitis media' and define this to mean 'a chronic perforation with chronic otitis media'.

Resolution: new classification

Hitherto, the definition of chronic otitis media has been either that of a clinical syndrome, or as a mixture of pathological entity and clinical syndrome. The tension seems most easily resolved by considering chronic otitis media to be a purely pathological entity.

- 'Chronic otitis media' is a pathological term only, indicating chronic inflammation affecting the middle ear cleft.
- **Chronic otitis media may be attended by various pathological complications affecting the structures of the middle ear cleft, including perforated tympanic membrane, tympanic membrane retraction pockets, cholesteatoma, ossicular defects, tympanosclerosis and myringitis.**
- The patient may be troubled by symptoms and signs caused by a mixture of these pathologies.

This framework (see **Figure 74.1**) provides the basis for the organization of this chapter, since this model predicts:

- multiple complications of chronic otitis media may present simultaneously (see **Figure 74.1** and **74.2**);
- treatment of an ear affected by chronic otitis media may require attention to each of many complications;
- treatment of complications of chronic otitis media does not necessarily influence the severity of the underlying chronic otitis media;
- the treated ear remains at risk of further complications of chronic otitis media.

The last of these points is of particular importance when considering chronic otitis media in children. If otitis media in children is more vigorous than in adults, it is possible to predict further that the complications of chronic otitis media are more prevalent in children than in adults; and the outcomes of the treatment of ears affected by chronic otitis media in children, particularly in the long term, are worse than in adults. These two assertions clearly justify a greater understanding of this condition in children and are examined throughout this chapter.

Table 74.1 Recent advances in classification of otitis media.

Classification			
Otitis media	Acute otitis media		
	Otitis media with effusion		
Eustachian tube dysfunction			
Intratemporal (extracranial) complications	Perforation of tympanic membrane	Acute perforation Chronic perforation	Acute otitis media Chronic otitis media (and mastoiditis; chronic suppurative otitis media)
	Mastoiditis		
	Apical petrositis	Acute Chronic	
	Facial paralysis	Acute Chronic	
	Labyrinthitis	Acute Serous Suppurative Chronic	
	Atelectasis of middle ear	Localized Generalized	
	Aural acquired cholesteatoma	Without infection With infection	
	Cholesterol granuloma		
	Ossicular discontinuity		
	Adhesive otitis media		
	Tympanosclerosis		
	Ossicular fixation		
Intracranial complications	Meningitis		
	Extradural abscess		
	Subdural ernpyema		
	Encephalitis		
	Brain abscess		
	Dural sinus thrombosis		
	Hydrocephalus		

Modified from Ref. 3, with permission. This classification is widely recognized, but the concepts which underpin it are not used in this chapter. Please refer to Resolution: new classification and Figure 74.1.

HISTOLOGY AND PATHOGENESIS OF CHRONIC OTITIS MEDIA

Histological analysis of human temporal bones with various types of otitis media has revealed that although the clinical subgroups of otitis media may be considered to be distinct, the histology of these groups overlaps considerably.^{4,5}

- All forms of otitis media display submucosal inflammatory infiltrates and mucosal metaplasia with the development of glandular structures, mucus-producing cells and ciliated cells on histological examination.
- Chronic inflammation is characterized by tissue destruction, as well as attempts at healing.

- The general histological features include mononuclear cell infiltrates, submucosal fibrosis, the formation of highly vascular granulation tissue and osteitis.
- Mucosal complications such as cholesterol granuloma and tympanosclerosis may be seen.
- Changes in special structures associated with the middle ear cleft, such as the tympanic membrane, are also seen.
- It is of particular importance that histologically discernible chronic otitis media occurs quite frequently in the absence of tympanic membrane perforation.⁴
- Animal experiments indicate that features of chronic inflammation appear within 14 days if acute otitis media fails to resolve.⁶

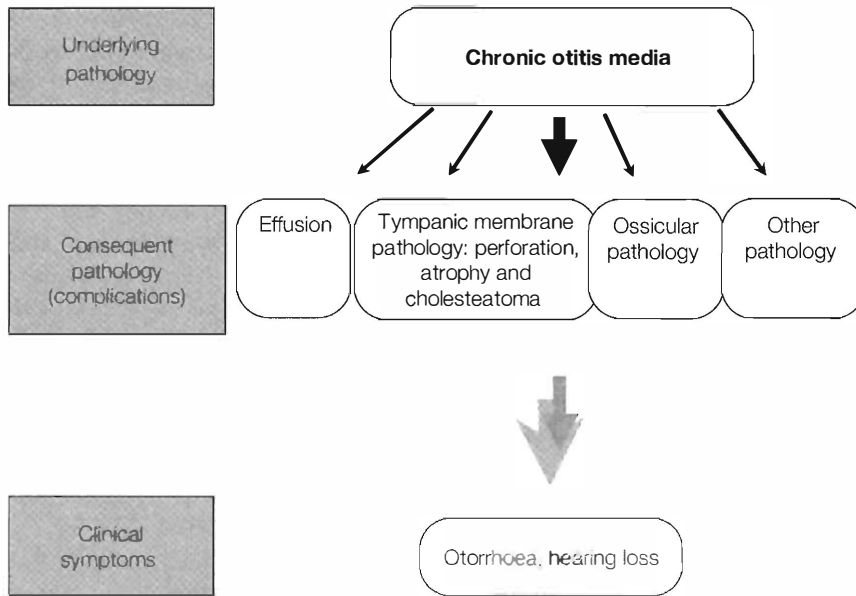

Figure 74.1 Model for the classification of chronic otitis media. In this model, chronic otitis media is regarded as a pathological entity only. The arrows indicate a one-way relationship. Thus, chronic otitis media may be complicated by a wide variety of largely independent pathological complications and the clinical presentation is governed by which complications are present. This model predicts that treatment of a complicating pathology will not influence the nature of the underlying chronic otitis media, a problem of considerable significance in the management of this disease in children.

© Hedder Arnold / Scott Brown 7E

Figure 74.2 Chronic otitis media and its complications. In this ear chronic otitis media has been complicated by tympanic membrane perforation, tympanic membrane sclerosis, tympanic membrane atrophy, ossicular erosion and erosion of the posterior annulus. Although gross inspection suggests the middle ear mucosa to be healthy, published histological survey has established that microscopic analysis will confirm the presence of chronic inflammation.

WHAT MAY PREVENT RESOLUTION OF OTITIS MEDIA?

Repeated infection from the nasopharynx

Acute upper respiratory tract infections may spread to the middle ear cleft from the nasopharynx via the Eustachian

tube. The following mechanisms are suggested to enhance transfer between the nasopharynx and middle ear.

- In the presence of an intact tympanic membrane, inflammation of the pharyngeal end of the Eustachian tube may prevent gas exchange along the Eustachian tube. Isolation of the middle ear allows diffusion effects with the middle ear mucosa to dominate the physiology of the middle ear cleft gas pocket. Over long periods this results in lowering of the middle ear pressure. In turn, this may predispose to aspiration of nasopharyngeal microbes into the middle ear cleft on the rare occasion when the Eustachian tube does manage to open.
- In the presence of a perforated tympanic membrane, the middle ear air cushion no longer impedes the movement of gas from the nasopharynx into a closed box, predisposing to reflux from the nasopharynx to the middle ear cleft.⁷

Repeated infection from the external ear canal

In the presence of a perforated tympanic membrane, microbes can be transported in fluid media from the ear canal into the middle ear. In particular, water that gains access to the external ear canal can flow without impediment into the middle ear through the perforation. In addition, mucus from the middle ear may straddle the tympanic membrane and provide a vehicle for the transfer of microbes from the external ear into the mesotympanum.

Persistent colonization by bacterial biofilms

There is evidence that many chronic infections are caused by the ability of bacteria to alter their form to create

nonmotile communities adherent to mucosa and protected by polysaccharide matrix. Such biofilms are able to resist most forms of host resistance as well as antibiotics and are not detected by conventional microbiological assays. The biofilms often consist of many microbial strains and are capable of converting back to more conventional planktonic bacterial populations. Biofilms have long been recognized in chronic infections.⁸ Recent microscopic evidence of biofilms in otitis media has indicated that this mechanism may be important in maintaining chronic ear infections.⁹

CHRONIC PERFORATION OF THE TYMPANIC MEMBRANE

Definitions

According to the panel reporting to the Seventh Post-Symposium Research Conference of the International Symposium on Recent Advances in Otitis Media a perforation of the tympanic membrane is deemed to be chronic if present for three months.³ Chronic suppurative otitis media is defined by otorrhoea of at least six weeks duration in the presence of a chronic tympanic membrane perforation.³

By contrast, the WHO defines chronic suppurative otitis media as 'a stage of ear disease in which there is chronic infection of the middle ear cleft, i.e. Eustachian tube, middle ear and mastoid, and in which a non-intact tympanic membrane (e.g. perforation or tympanostomy tube) and discharge (otorrhoea) are present'.¹ The same report qualifies this definition by stating that the otorrhoea should be present for two weeks or longer.¹

Chronic otitis media and the pathology of tympanic membrane perforation

Tympanic membrane perforation usually occurs secondary to acute otitis media. The process by which acute traumatic tympanic membrane perforations heal has been studied in animals. These investigations indicate that healing is mediated by hyperplasia, proliferation and migration of the outer keratinizing squamous epithelium.¹⁰ This advances ahead of connective tissue rich in fibroblasts. Failure of this process has been attributed primarily to persistent infection.

One study examined 30 entire perforated tympanic membranes taken from patients receiving tympanic allografts for the treatment of their perforations. All showed evidence of inflammation, epithelial hyperplasia and fibrosis as if still trying to heal.¹¹ A second study of the margins of surgically treated chronic perforations indicated that the connective tissue was inadequately vascularized and extracellular matrix substances and

growth factors were deficient. In 5 of the 30 cases in the former study, squamous epithelium extended medially more than 0.7 mm from the perforation edge.¹¹

A tympanic membrane perforation associated with chronic otitis media is not just a defect in an otherwise normal structure. Not only is the tympanic membrane participating in the chronic inflammation, but the endoepithelial junction need not be located at the perforation edge.

Chronic otitis media need not be associated with tympanic membrane changes.¹² By contrast, inflammatory changes in the tympanic membrane are almost universally associated with chronic otitis media.¹²

Classification

Older textbooks distinguish between tubotympanic disease, which is a defect of the anterior and inferior tympanic membrane and atticointral disease, which is a defect of the posterior and superior tympanic membrane. The former group is also termed safe and the latter unsafe.

Older textbooks also distinguish between central and marginal perforations.

These classifications do not clearly distinguish tympanic membrane perforation from other tympanic membrane pathology, such as retraction pockets or cholesteatoma. By grouping a number of complications of chronic otitis media, these classifications draw conclusions about their combined behaviour instead of informing us about perforations alone.

There is no evidence that true perforations (perforations with no retraction) in the epitympanum and posterior mesotympanum behave differently from other tympanic membrane perforations. However, tympanic membrane disease affecting the epitympanum and posterior mesotympanum is more likely to be cholesteatoma or a retraction pocket. These do behave differently to perforations.

There is no evidence that true marginal perforations behave differently from other tympanic membrane perforations. However, marginal tympanic membrane disease is more likely to be cholesteatoma or a retraction pocket. These do behave differently to perforations.

As both perforations and retractions can affect any part of the tympanic membrane, a classification based on tympanic membrane locations is not an accurate means of distinguishing between them.

These classifications attempt on an anatomical basis to distinguish tympanic membrane pathologies which behave differently from one another. It is more germane to distinguish between tympanic membrane perforation and tympanic membrane retraction pockets (including cholesteatoma). This distinction is not difficult to make with the help of the otological microscope.

There is evidence that granulation tissue, which is a feature of all forms of chronic otitis media, can also give

rise to acute intracranial infections. Thus even the distinction between cholesteatoma and perforations is not a valid means of identifying safe and unsafe disease.¹³

Epidemiology

The epidemiology of chronic ear discharge associated with chronic ear perforations (chronic suppurative otitis media) has been widely studied in children. The WHO recognize a prevalence of chronic suppurative otitis media of more than 1 percent of children as presenting an 'avoidable burden' which can be managed in the 'general health care context'¹ and more than 4 percent as representing a 'massive' public health problem requiring urgent attention.¹

The populations with the highest prevalence of childhood chronic suppurative otitis media are found among the Inuit and Australian Aboriginals. The most extreme rates of tympanic membrane perforation in a series have been recorded at 67 percent in Australian Aboriginals and 46 percent in the Inuit.^{14, 15} Apache and Navaho Indians, rural Maori and Solomon Islanders as well as some rural Indian and African populations have been found to have a point prevalence of chronic suppurative otitis media of over 5 percent. Other Native American, Indian and African populations have prevalence rates of 1–2 percent.¹

Prospective studies of large populations of urban children in Saudi Arabia and Brazil found point prevalence of chronic suppurative otitis media of 1.3 and 0.9 percent, respectively.^{16, 17} A well-planned national study in South Korea found a rate of less than 1 percent in the paediatric population.¹⁸
